Figure 77.12 MONITORING MINIMAL RESIDUAL DISEASE IN HAIRY CELL LEUKEMIA. (A) Total nucleated cells in a hemodilute bone marrow aspirate (*a* and *b*); total lymphocytes (*c* to *e*). Hairy cells (*red*, about 6% of total cellularity and 12% of lymphocytes) show increased side scatter *(SSC)* because of their high cytoplasmic complexity, compared with normal B cells *(blue)*. Hairy cells often show increased expression of CD20 *(a)*. On CD45 versus SSC gating plots *(b)*, they may be mistaken for monocytes. Hairy cells usually show bright expression of CD11c and CD22 *(c)* and CD25 *(d)* and are positive for CD103 *(e)*. (B) Total lymphocytes from a posttherapy bone marrow aspirate, positive for minimal residual hairy cell leukemia, accounting for about 0.6% of total cellularity. Hairy cells *(red)* can be easily distinguished from normal B cells *(blue)*, particularly on the basis of their bright expression of CD11c *(a)* and CD25 *(b)* and positivity for CD103 *(c)*. In *a*, 30,000 total cells were collected; in *b* and *c*, 100,000. *(Courtesy Jeffrey Jorgensen, Department of Hematopathology, UTMDACC.)*

analogue in each case. The overall response rate was 80% with 30% achieving a CR. Remarkably, for those patients with a CR, the clinical benefit persisted for 21 to 60.5 months. As with vemurafenib, there was no hematological toxicity associated with dabrafenib. A prospective trial combining dabrafenib with the MEK inhibitor, trematinib, has also reported very high and durable responses in patients with relapsed HCL. Trials combining BRAF inhibitors with rituximab or with other CD20-directed monoclonal antibodies are ongoing. These studies suggest that BRAF inhibitors are promising agents for HCL patients who are unresponsive or refractory to purine analogs. The role of these agents alone or in combination with other novel agents will require further investigation.

Incidence of Second Malignancies

Early studies suggested an association between HCL and development of second malignancies, but this link is controversial and has been refuted by other reports. The reported second cancers include melanoma, prostate cancer, gastrointestinal cancers, and non-Hodgkin lymphomas. Whether these second malignancies are related to the primary disease itself or to its treatment has also been debated. A number of long-term studies of patients treated with pentostatin or cladribine have not shown a statistically significant increased risk for second malignancies. In a prospective long-term follow-up study of cladribine in 221 HCL patients performed at three different centers in Switzerland, 19.95% of patients developed a second primary malignancy. These malignancies were the main cause of death, but this rate was not higher than the incidence of primary tumors in a normal matched Swiss population. To date, the relationship between HCL treatment and second primary malignancies remains controversial.

FUTURE DIRECTIONS

Over the past decade, success in the treatment of HCL has led to diminished interest in developing new therapeutic strategies for treating this uncommon leukemia, with research confined to a few specialized centers interested in the biology and pathogenesis of this disease. Recent reports unraveling the biologic and molecular aspects of the disease have kindled a significant resurgence of interest.[2,7,43,44] Further studies into other aspects of the disease such as the role of microenvironment, BCR signaling, and the complex interaction of various signaling pathways will likely provide better therapeutic tools and strategies.[45]

CHAPTER 78

THE PATHOLOGIC BASIS FOR THE CLASSIFICATION OF NON-HODGKIN AND HODGKIN LYMPHOMAS

Girish Venkataraman, Elaine S. Jaffe, and Stefania Pittaluga

INTRODUCTION AND HISTORICAL BACKGROUND

The classification of malignant lymphomas has undergone significant changes over the past 50 years. The current approach is based on the integration of morphologic, phenotypic, genetic, and clinical features that allows the identification of distinct disease entities (see box on Principles of the Classification of Lymphomas). This practical approach to lymphoma categorization was initially proposed by the International Lymphoma Study Group in 1994 and formed the basis of the Revised European–American Classification of lymphoid neoplasm (REAL). It was then adopted by the World Health Organization (WHO) classification of neoplasm of the hematopoietic and lymphoid tissues published in 2001, updated in 2008, and revised again in 2017 (Table 78.1).[1–3] The WHO classification represents a significant achievement in terms of cooperation, communication, and consensus among pathologists, hematologists, and oncologists. Furthermore, it recognizes that for any classification system to be viable and applicable, it should evolve and incorporate new data resulting from emerging technologies in the field of hematopathology such as the results from genome-wide large-scale sequencing studies. These studies have led to the identifications of new prognostic and diagnostic categories, and provide insight into therapeutic targets based on a better understanding of molecular mechanisms of transformation. This chapter focuses on the classification of neoplasms derived from mature B cells, T cells, and natural killer (NK) cells with an emphasis on malignant lymphoma. We provide a framework for the subsequent chapters on Hodgkin and non-Hodgkin lymphomas in reviewing the major entities according to the WHO classification.

PRINCIPLES OF THE CLASSIFICATION OF LYMPHOMAS BASED ON THE REVISED EUROPEAN–AMERICAN CLASSIFICATION OF LYMPHOID NEOPLASM/WORLD HEALTH ORGANIZATION CLASSIFICATIONS

- Each disease is defined as a distinct entity based on a constellation of morphologic, clinical, and biologic features.
- The cell of origin is the starting point of disease definition.
- Some lymphoid neoplasms can be identified by routine morphologic approaches. However, for most diseases, knowledge of the immunophenotype and molecular genetics/cytogenetics plays an important role in differential diagnosis.
- A disease-based approach to classification facilitates the discovery of molecular pathogenesis.
- The sites of presentation and involvement are important clues to underlying biologic distinctions. Extranodal lymphomas differ in many respects from their nodal counterparts.
- Many lymphoma entities display a range in cytologic grade and clinical aggressiveness, making it difficult to stratify lymphomas according to clinical behavior. A number of prognostic factors influence clinical outcome, including stage, international prognostic index, cytologic grade, gene expression profile, secondary genetic events, and the host environment.

MATURE B-CELL NEOPLASMS

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) usually presents in adults with generalized lymphadenopathy, frequent bone marrow and peripheral blood involvement, and often hepatosplenomegaly. Presentation as leukemia, that is, CLL, is more common than as lymphoma, SLL. Even in patients with a lymphomatous presentation, careful examination of the blood may reveal a circulating monoclonal B-cell component. Nevertheless, there are some patients who will present with generalized adenopathy, and whereas progression to CLL is frequent, it does not necessarily occur in all cases.

The increased sensitivity of immunophenotypic/molecular methodologies has resulted in the detection of clonal lymphoid proliferations with a CLL phenotype in the general population, even in the absence of clinical lymphocytosis, a condition now designated monoclonal B-cell lymphocytosis (MBL) (see box on Early Events in Lymphoid Neoplasia). The International Workshop on CLL proposed new diagnostic criteria that were then included in the WHO classification of 2008. Recent studies have distinguished between high count and low count MBL, with a count of monoclonal B cells greater than 5.0 × 10^3/L being more clinically significant.[4] Similar to peripheral blood, small clonal populations with a CLL phenotype can be detected in lymph nodes as an incidental finding and appear to represent a tissue counterpart of MBL.[5] Histologically, the lymph node involved by CLL/SLL shows diffuse architectural effacement (Fig. 78.1), although occasional residual naked germinal centers can be observed. The predominant cell type is a small lymphocyte with

EARLY EVENTS IN LYMPHOID NEOPLASIA

- In recent years, there has been a greater appreciation of early events in lymphoid neoplasia.
- These early lesions can in some ways be considered equivalent to benign neoplasms in the epithelial system and require special management approaches.
- These are clonal proliferations of B cells or T cells that carry genetic aberrations associated with specific forms of lymphoid neoplasia: CLL, multiple myeloma, follicular lymphoma, and mantle cell lymphoma.
- Examples include: MGUS, MBL, in situ follicular neoplasia, and in situ mantle cell neoplasia.
- Early lesions appear to lack the secondary and tertiary “hits” seen in lymphoid neoplasms that are clinically significant, and most patients have a very low risk of clinical progression.
- Challenges for the future are:
  - to define the precise genetic features that distinguish early lesions from lymphoma
  - to assess the risk of clinical progression
  - to determine how these patients should be managed clinically.

CLL, Chronic lymphocytic leukemia; *MBL*, monoclonal B-cell lymphocytosis; *MGUS*, monoclonal gammopathy of undetermined significance.

TABLE 78.1 World Health Organization Classification of Lymphomas[a]

Mature B-Cell Neoplasms

- ***Chronic lymphocytic leukemia/small lymphocytic lymphoma***
- B-cell prolymphocytic leukemia
- Splenic B-cell marginal zone lymphoma
- Hairy cell leukemia
- *Splenic B-cell lymphoma/leukemia, unclassifiable*
  - *Splenic diffuse red pulp small B-cell lymphoma*
  - *Hairy cell leukemia-variant*
- Lymphoplasmacytic lymphoma
  - Waldenström macroglobulinemia
- Heavy chain diseases
- ***Plasma cell myeloma***
  - Plasmacytoma
- ***Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)***
- Nodal marginal zone lymphoma
  - *Pediatric nodal marginal zone lymphoma*
- ***Follicular lymphoma***
  - *Pediatric-type follicular lymphoma*
- Primary cutaneous follicle center lymphoma
- ***Mantle cell lymphoma***
- ***Diffuse large B-cell lymphoma (DLBCL), NOS***
  - T-cell/histiocyte–rich large B-cell lymphoma
  - Primary DLBCL of the CNS
  - Primary cutaneous DLBCL, leg type
  - EBV-positive DLBCL, NOS
  - DLBCL associated with chronic inflammation
- Lymphomatoid granulomatosis
- Primary mediastinal (thymic) large B-cell lymphoma
- Intravascular large B-cell lymphoma
- ALK-positive large B-cell lymphoma
- Plasmablastic lymphoma
- Primary effusion lymphoma
- Burkitt lymphoma
- High-grade B-cell lymphomas, with *MYC* and *BCL2* and/or *BCL6* rearrangements
- B-cell lymphoma unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classic Hodgkin lymphoma

Mature T-Cell and NK-Cell Neoplasms

- T-cell prolymphocytic leukemia
- T-cell large granular lymphocytic leukemia
- *Chronic lymphoproliferative disorder of NK-cells*
- Aggressive NK-cell leukemia
- Systemic EBV-positive T-cell lymphoma of childhood
- Hydroa vacciniforme-like lymphoproliferative disorder
- Extranodal NK/T-cell lymphoma, nasal type
- Adult T-cell leukemia/lymphoma
- Enteropathy-associated T-cell lymphoma
- Monomorphic epitheliotropic intestinal T-cell lymphoma
- Hepatosplenic T-cell lymphoma
- Subcutaneous panniculitis-like T-cell lymphoma
- ***Mycosis fungoides***
- Sézary syndrome
- Primary cutaneous CD30-positive T-cell lymphoproliferative disorders
  - Lymphomatoid papulosis
  - Primary cutaneous anaplastic large cell lymphoma
- Primary cutaneous gamma-delta T-cell lymphoma
- Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma
- Primary cutaneous CD4-positive small/medium T-cell lymphoproliferative disorder
- ***Peripheral T-cell lymphoma, NOS***
- ***Angioimmunoblastic T-cell lymphoma***
- Nodal peripheral T-cell lymphoma with T-follicular helper phenotype
- Anaplastic large cell lymphoma, ALK-positive
- Anaplastic large cell lymphoma, ALK-negative

Hodgkin Lymphoma

- Nodular lymphocyte predominant Hodgkin lymphoma
- Classic Hodgkin lymphoma
  - ***Nodular sclerosis Hodgkin lymphoma***
  - Lymphocyte-rich classic Hodgkin lymphoma
  - Mixed-cellularity classic Hodgkin lymphoma
  - Lymphocyte-depleted classic Hodgkin lymphoma

[a] Most common entities are bold and italicized. Provisional entities are in non-bold italics. Some rare entities or variants are omitted (see reference 3 for complete list).
ALK, Anaplastic lymphoma kinase; *CNS*, central nervous system; *EBV*, Epstein-Barr virus; *NK*, natural killer; *NOS*, not otherwise specified.

clumped chromatin, but a spectrum of nuclear morphology is usually seen. Pseudofollicular growth centers or proliferation centers are present in the majority of cases and contain a spectrum of cells ranging from small lymphocytes to prolymphocytes and paraimmunoblasts. The prolymphocytes and paraimmunoblasts have more dispersed chromatin and more prominent nucleoli usually centrally placed. The presence of proliferation centers is also a helpful criterion in the differential diagnosis with mantle cell lymphoma (MCL), which may show otherwise some overlapping features with CLL. If needed, immunophenotypic studies can be helpful in this differential diagnosis.

CLL/SLL is characterized by $CD5^+$, $CD23^+$, $LEF1^+$ B cells expressing dim CD20, and usually dim surface immunoglobulin (sIg). Cyclin D1 is negative, in contrast to MCL. CLL has been shown to have a greater degree of heterogeneity biologically, and different subgroups have been identified based on immunoglobulin (Ig) heavy-chain mutational status, cytogenetics, ZAP-70 expression, and CD38 expression. The latter two have been used as partial surrogate markers for the mutational status. ZAP-70 expression correlates with an unmutated status and poorer prognosis (Fig. 78.1). In fact, ZAP-70 expression has been suggested to be more clinically relevant than mutation status when the two markers are discordant. The use of CD38 as surrogate marker for mutational status is less useful, but its high expression is also associated with a poor prognosis. Recently, recurrent somatic mutations have been identified in a subset of CLL patients using whole-genome and exome sequencing techniques, and some of them have been associated with clinical outcome and may be useful in the future for risk stratification including CLL-International

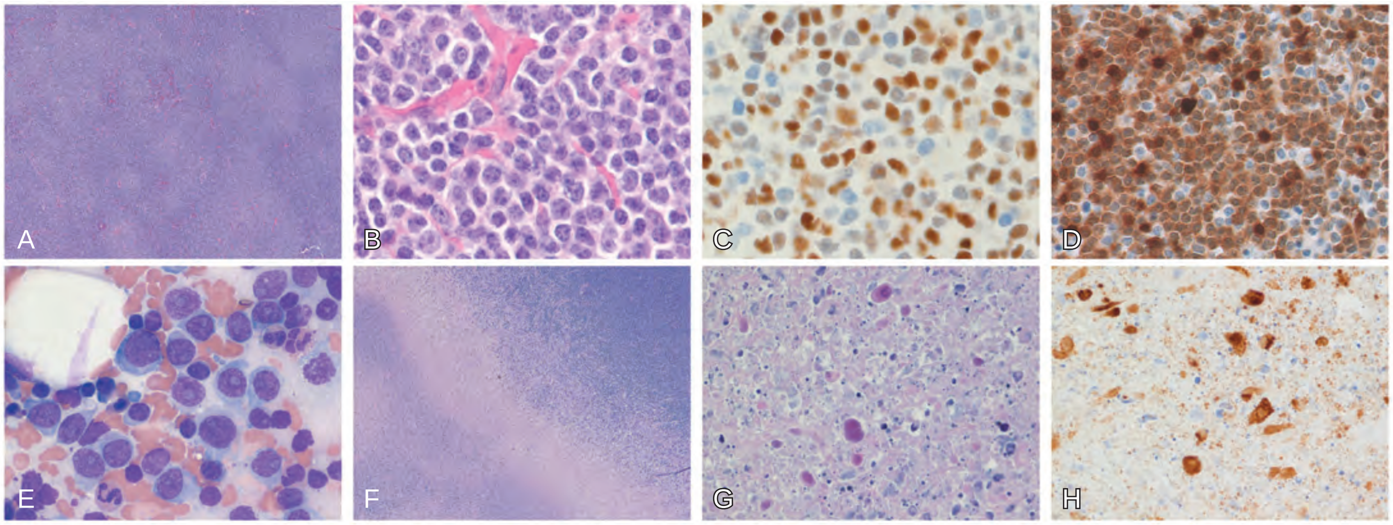

Figure 78.1 SMALL LYMPHOCYTIC LYMPHOMA. Low-power view (A) illustrates a diffuse effacement of the lymph node with scattered pale nodules corresponding to growth centers. A monotonous population of small lymphocytes is seen at higher power (B). The lymphoma cells are positive for LEF1 (C) and ZAP70 with scattered normal T-cells staining brightly for ZAP70 (D). Accelerated prolymphocytoid transformation shows increased numbers of large prolymphocytes in the marrow with prominent nucleoli (E). Patients, especially after fludarabine therapy, can develop worsening lymphadenopathy from viral infections such as herpes simplex virus, in which the node typically shows focal necrosis bottom left (F) with typical Cowdry nuclear inclusions in the necrotic areas at higher power (G) confirmed with immunohistochemistry for herpes simplex virus (H).

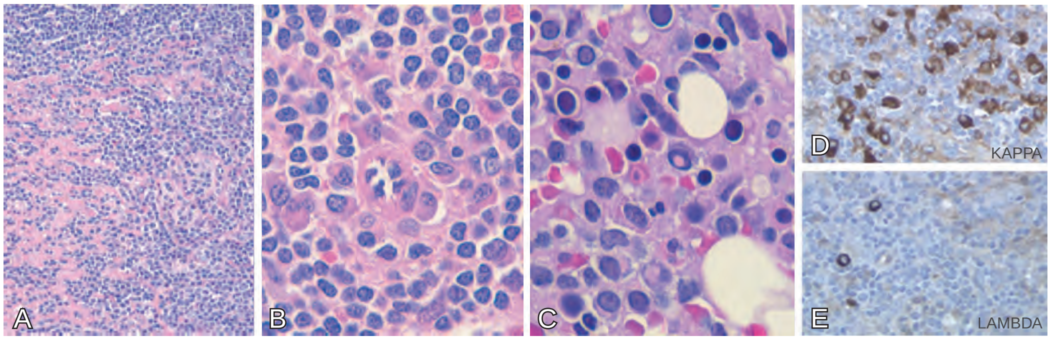

Figure 78.2 LYMPHOPLASMACYTIC LYMPHOMA (LPL). Lymphoplasmacytic lymphoma and Waldenström macroglobulinemia have nearly identical morphology. There is a diffuse infiltrate (A) of small lymphocytes that have plasmacytoid features or interspersed plasma cells (B). Intranuclear inclusions can sometimes be seen (C). Evaluation for κ and λ by immunohistochemical stains can demonstrate clonality in the plasma cells and plasmacytoid lymphocytes (D) and (E). This case shows kappa light chain restriction.

Prognostic Index (IPI). In addition, deletions at 17p, or mutations in TP53 correlate with a more aggressive clinical course.[6]

Histologic transformation over time may occur in CLL, a phenomenon known as Richter syndrome. Short of progression to diffuse large B-cell lymphoma (DLBCL), lymph nodes may show an increased number of prolymphocytes and paraimmunoblasts, sometimes referred to as "accelerated phase" or "prolymphocytoid" transformation (Fig. 78.1E). The two overt lymphomatous forms of Richter transformation include classic Hodgkin lymphoma (CHL) and more commonly, DLBCL. While a significant proportion of CHL cases are Epstein-Barr virus (EBV) associated, most DLBCLs are unrelated to EBV.[7] Treatment with immunosuppressive agents such as fludarabine appears to increase the risk of transformation.

Lymphoplasmacytic Lymphoma

The definition of lymphoplasmacytic lymphoma (LPL) and its relationship to other B-cell lymphomas associated with plasmacytoid differentiation and monoclonal gammopathy has been clarified in recent years. LPL is frequently associated with Waldenström macroglobulinemia (WM). The 2008 WHO classification adopted the approach advocated at the second international workshop on WM, which defined WM as the presence of an immunoglobulin M (IgM) monoclonal gammopathy of any concentration associated with bone marrow involvement by LPL.[8] Hence, LPL and WM are not synonymous, with WM defining a subset of LPL.

More recently, recurrent mutations in MYD88 (L265P) have been identified in greater than 90% of WM patients and are highly associated with LPL but infrequently seen in other B-cell lymphomas with plasmacytoid features, such as marginal zone lymphomas. In addition, nonsense and frameshift mutations involving CXC-chemokine receptor 4, similar to those occurring in warts hypogammaglobulinemia infections myelokathexis (WHIM) patients, were reported and are associated with heavy disease burden.

LPL is a disease of adult life that usually presents with bone marrow involvement and sometimes with nodal and splenic involvement (splenomegaly), vague constitutional symptoms, and anemia (see Chapter 92). The tumor consists of a diffuse proliferation of small lymphocytes, plasmacytoid lymphocytes, and plasma cells, with or without Dutcher bodies (Fig. 78.2). The growth pattern is often interfollicular, with sparing of the sinuses. The cells have surface and cytoplasmic Ig, usually of IgM type, usually lack IgD, and express B-cell-associated antigens (CD19, CD20, CD22, CD79a). They are usually negative for CD5 and CD10. CD25 or CD11c may be weakly expressed in some cases. The lack of CD5 and the presence of strong cytoplasmic Ig are useful in the distinction from CLL. The postulated normal counterpart is thought to be a postfollicular B-cell-based in part on the presence of somatic mutations in the Ig heavy and light-chain variable region genes.

Mantle Cell Lymphoma

MCL is a distinct entity that has been more precisely defined in recent years through the integration of immunophenotypic, molecular genetic, and clinicopathologic studies.[9] The molecular hallmark of MCL is the t(11;14)(q13;q32) involving Cyclin D1 (*CCND1*) and the *IGH* gene. Cyclin D1 overexpression is believed to be essential in the pathogenesis of MCL. However, rare variants negative for Cyclin D1 with similar immunomorphology and gene expression signature have been identified, and most often have translocations involving *CCND2*. Sox11 is overexpressed in most Cyclin D1 positive and negative cases.[10] The postulated normal counterpart is the $CD5^+$, $sIgM^+$ and $sIgD^+$, "naïve" B cell that can be found in the peripheral blood and mantle zones of reactive germinal centers. Mutational analysis of the rearranged Ig variable region genes shows few or no somatic mutations; however, similarly to CLL, a subset of MCL has mutated *IG* genes.

Recently, because of the widespread use of immunohistochemistry (IHC), early involvement of lymph node by cells carrying t(11;14) translocation with subsequent overexpression of Cyclin D1 has been documented in several cases, referred to initially in the WHO 2008 as "in situ MCL" but now termed "in situ MC Neoplasia" (in situ MCN) in the WHO 2017 update, reflecting that this is an early lesion. Most often, these represent an incidental finding, but some cases will eventually progress to overt MCL.[5] In some cases, in situ MCN is detected in a lymph node involved by another lymphoma type, such as follicular lymphoma (FL). The risk of progression of in situ MCN is difficult to ascertain, as the number of reported cases is few. In a recent multicentric retrospective study, it was noted that the expression of Sox11 was more frequently associated with progression to MCL since the majority of in situ cases lacked Sox11 expression. Also, similar to in situ follicular neoplasia (ISFN), a distinction should be made between partial involvement by MCL with a mantle zone pattern and in situ MCN. The latter refers to a reactive lymph node with Cyclin D1 positive cells limited to an otherwise normal-appearing follicle mantle.

Another newly identified variant is an indolent form of MCL characterized by a leukemic phase without nodal disease, but often with long-standing splenomegaly. These patients have an indolent clinical course and do not appear to require aggressive chemotherapy. These cases carry t(11;14) with few additional chromosomal abnormalities and lack the expression of Sox11 in contrast to conventional MCL.

MCL occurs in adults (median age 62), with a high male-to-female ratio. Most patients present with advanced stage at diagnosis. Common sites of involvement include lymph nodes, spleen, bone marrow, and lymphoid tissue of Waldeyer ring. Gastrointestinal (GI) tract involvement is frequent and is associated with the picture of lymphomatous polyposis.

The hallmark of MCL is a very monotonous cellular composition. In the typical case, the cells are slightly larger than a normal lymphocyte with finely clumped chromatin, scant cytoplasm, and inconspicuous nucleoli (Fig. 78.3). The nuclear contour is usually irregular or cleaved. Some cytologic variants, blastoid and pleomorphic, tend to be associated with a more aggressive course and adverse biologic features, such as tetraploidy or p53 mutation/deletion. The proliferation rate was previously identified as prognostically important based on the scoring of $Ki67^+$ cells (<10%, 10% to 30%, and >30%). More recently, gene expression profiling (GEP), using genes involved in cell cycle progression and DNA synthesis, has identified a proliferation signature that delineates cohorts with varied prognoses. These correlate to some extent with cytologic subtypes. For example, the blastoid variant has a high proliferation rate, utilizing both KI-67 and GEP signature. More recent data indicate that high P53 expression (>20%) has adverse prognostic significance independent of KI-67 or the MCL-IPI.[11]

Follicular Lymphoma

FL is the most common subtype of non-Hodgkin lymphoma within the United States and accounts for approximately 45% of all newly diagnosed cases. It has a peak incidence in the fifth and sixth decades and is rare under the age of 20. Men and women are equally affected. FL is less common in Black and Asian populations. Most patients have stage 3 or 4 disease at diagnosis, with generalized lymphadenopathy. Staging evaluation will usually detect bone marrow involvement. Approximately 10% of patients will have circulating malignant cells. However, careful immunophenotypic or molecular analyses may disclose peripheral blood involvement in a higher proportion of patients. A more accurate prognostic index than the IPI, the FL IPI, has been proposed for FL and has been widely adopted.

The natural history of the disease is associated with histologic progression in both pattern and cell type (Fig. 78.4). A heterogeneous cytologic composition is one of the hallmarks of FL. Usually, all of the follicle center cells are represented, but in varying proportions. It should be stressed that the variation in cytologic grade is a continuum, and therefore, precise morphologic criteria for subclassification are difficult to establish.

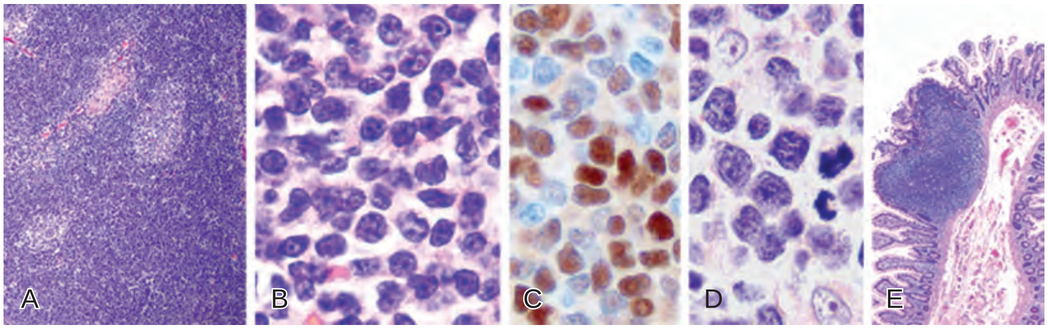

Figure 78.3 MANTLE CELL LYMPHOMA. At low power, mantle cell lymphoma (MCL) can show a diffuse, vaguely nodular, or mantle zone pattern. In the latter, the neoplastic mantle zones are expanded and can become confluent leaving "naked" germinal centers (A). At higher power, the lymphoma cells are small or slightly enlarged (B). They have irregular nuclear contours, especially compared with small lymphocytic lymphoma, and they have dense chromatin. Typically, cases are positive for cyclin D1 expression (C), which is related to the t(11;14) involving IgH and *CCND1*. Some cases can develop a "blastoid" transformation (D), although some cases can present as a "blastoid" variant. Such cases are characterized by cells with an intermediate size, a high mitotic rate, and finely dispersed "blastic" chromatin. Sometimes when the "blastoid" cases develop a leukemic phase, they can be difficult to distinguish morphologically from acute lymphoblastic leukemia. In such cases, flow immunophenotyping is needed to resolve the differential diagnosis. MCL can also present with gastrointestinal involvement (E) as in lymphomatous polyposis.

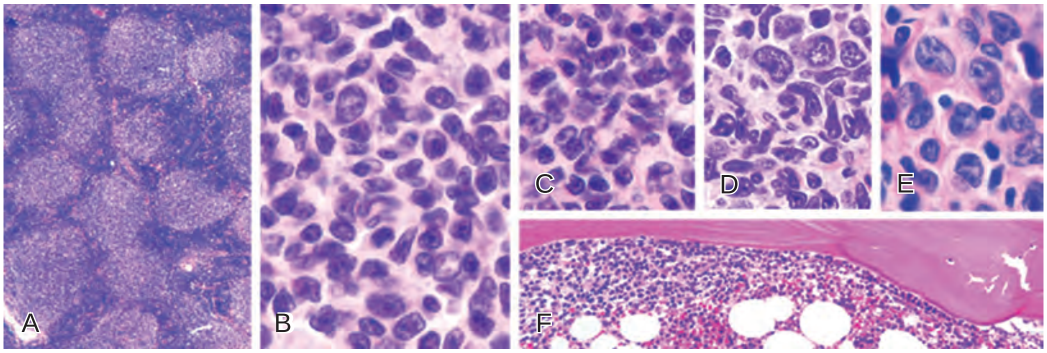

Figure 78.4 FOLLICULAR LYMPHOMA (FL). Follicular lymphoma (FL) shows effacement of the normal lymph node architecture because of an accumulation of neoplastic lymphoid follicles that lack the features of reactive follicles (A). They are crowded, show back-to-back localization, lack distinct mantle zones, and show no polarity. The lymphoma cells are highly irregular (B) with elongated, twisted, or clefted nuclear contours and dense chromatin. FL is typically graded into grade 1 or 2 (1/2; C, D), or 3 (E), depending on the number of large cells seen at higher power (see text). Large centrocytes should not be confused with centroblasts. FL typically involves the bone marrow with lymphoma cells spreading along the bone (F). This localization is termed "paratrabecular."

According to the WHO classification, all low-grade FL are combined into a single category, Grade 1–2, all containing overall a predominance of centrocytes with fewer than 15 centroblasts/high power field (hpf). FL grade 3 (with >15 centroblasts/hpf) is further subdivided into 3 A and 3B based on the presence or absence of centrocytes in the background.

The vast majority of FL (approximately 85%) are associated with a t(14;18) involving rearrangement of the *BCL2* gene. This translocation appears to result in constitutive expression of BCL2 protein, which is capable of inhibiting apoptosis in lymphoid cells. The cells of FL accumulate and are at risk to acquire secondary mutations, which may be associated with histologic progression. It has been postulated that the *BCL2/IGH* translocation occurs during Ig gene rearrangement in the bone marrow at the pre-B cell stage of development. This fact might contribute to the difficulty in eradicating the neoplastic clone with chemotherapy.

Biologically, the pathogenesis of most cases of FL grade 3B differs from that of FL grades 1–2/3 A, in lacking the *BCL2/IGH*, but also differs from DLBCL, in having a low incidence of *BCL6* aberrations.[12] These data provide a biologic explanation for the greater curability of grade 3B FL with aggressive therapy, although some studies have not found support for this hypothesis. Differences in diagnostic criteria might account for this apparent discrepancy, and the correlation between grade 3A versus 3B and molecular alterations is imprecise. Other phenotypic variants appear to have prognostic significance, such as FL negative for CD10 but positive for MUM1/IRF4. These cases are usually of higher grade and interestingly also lack the *BCL2* translocation. Evolution toward a molecularly defined classification of FL is a possibility for the future.

The phenomenon of localization of FL cells to isolated germinal centers within a lymph node has been termed ISFN.[5] The likelihood of evolution to clinically significant FL is low for these patients if there is no other evidence of disease at the time of diagnosis. Indeed, this translocation can be found in the peripheral blood and lymphoid organs of healthy individuals and suggests that the *BCL2/IGH* translocation is necessary but not sufficient for the development of FL. ISFN should be distinguished from partial involvement by FL. In the true "in situ" lesion, clusters of B cells strongly positive for CD10 and BCL2 are localized to germinal centers in an otherwise reactive lymph node. It often represents an incidental finding in a lymph node biopsied for other reasons.

The 2017 WHO classification recognizes other lymphomas of follicle center derivation that may resemble nodal FL but exhibit significant differences either clinically or biologically.[3] These include diffuse follicular FL, pediatric forms of FL, primary intestinal FL ("duodenal-type"), and cutaneous lymphomas of follicle center cell derivation. Intestinal FL, most often presenting in the duodenum, is associated with the *BCL2/IGH* translocation but usually presents as isolated mucosal polyps with a low risk of dissemination. FL in the pediatric age group is histologically diverse. Most nodal cases are cytologically high grade, composed of blastoid cells, but are usually localized, and may be cured in a number of instances with surgical excision and carry underlying *TNFRSF14* and *MAP2K1* mutations.[13] This so-called pediatric type of FL may also be seen in adults more rarely and shows a strong male predominance. Another form of FL seen in children and young adults is associated with translocations involving *IRF4* and shows overexpression of MUM1 by IHC. These cases frequently present in a Waldeyer ring.[14]

There are rare variants of FL with a mainly diffuse growth pattern. These often present as bulky localized inguinal masses and lack the *BCL2* translocation but often have deletions at 1p36. Primary cutaneous follicle center lymphoma, which also frequently lacks the *BCL2* translocation and BCL2 expression, is now considered by the WHO classification as a separate entity. They usually present in the head or upper trunk and can be managed conservatively with local approaches. However, when BCL2 expression is detected, the possibility that this may represent a secondary site of involvement should be considered.

Extranodal Marginal-Zone Lymphoma of Mucosa-Associated Lymphoid Tissue Type

Most lymphomas of marginal-zone derivation present in extranodal sites and have the histopathologic and clinical features identified by Isaacson and Wright as part of the spectrum of mucosa-associated lymphoid tissue (MALT) lymphomas. MALT lymphomas are characterized by a heterogeneous cellular composition that includes marginal-zone or centrocyte-like cells, monocytoid B cells, small lymphocytes, and plasma cells (Fig. 78.5A). In most cases, large transformed cells are infrequent. Reactive germinal centers are nearly always present. When follicular colonization occurs, the process may simulate FL. Clonality is confirmed by molecular and or immunohistochemical studies.

MALT lymphomas have been described in nearly every anatomic site but are most frequent in the stomach, lung, thyroid, salivary gland, and lacrimal gland. Other less common sites of involvement include the orbit, breast, conjunctiva, bladder and kidney, and thymus gland. Widespread nodal involvement is infrequent, as is marrow involvement. The clinical course is usually quite indolent, and many patients are asymptomatic. MALT lymphomas tend to relapse in other MALT-associated sites.

MALT lymphomas of the salivary gland and thyroid are usually associated with a history of autoimmune diseases. *Helicobacter* gastritis is frequent in most patients with gastric MALT lymphomas. Other infectious agents have been described in MALT lymphomas involving skin (*Borrelia burgdorferi*), ocular adnexae (*Chlamydia psittaci*), and small intestine (*Campylobacter jejuni*); however, in this latter group, a

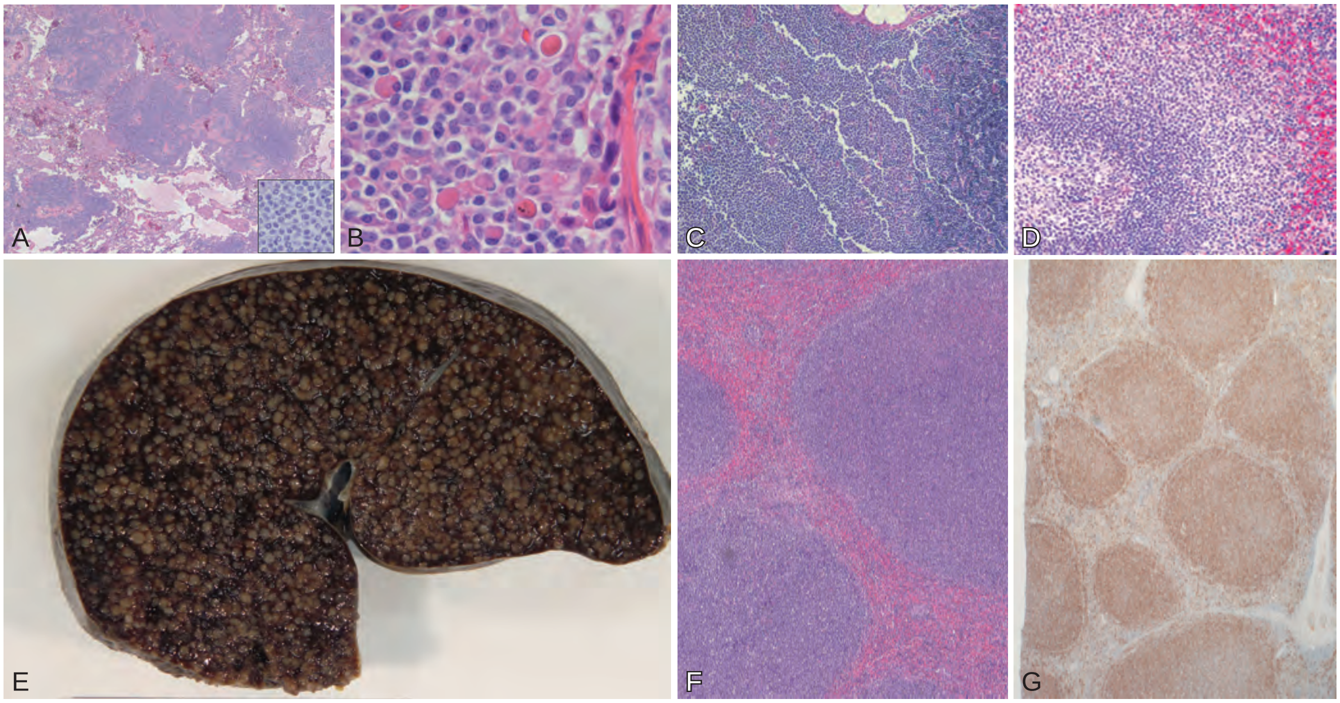

Figure 78.5 MARGINAL ZONE LYMPHOMA. Marginal zone lymphomas commonly occur at extranodal sites arising from mucosa-associated lymphoid tissue (MALT). MALT lymphomas typically infiltrate or invade into epithelial structures, resulting in "lymphoepithelial lesions" with multifocal nodular aggregates in the lung (A). They are composed of small to intermediate-sized cells with abundant clear cytoplasm (A, *detail bottom right*) with frequent plasmacytic differentiation and plasma cells filled with immunoglobulin ("Mott cells") (B). The normal lymph node does not have a marginal zone, but primary nodal marginal zone lymphomas (NMZL) can occur. They infiltrate the node in what would be a marginal zone pattern with an expansion of cells (C) peripheral to mantle zone seen at the right side. The spleen does however have a normal marginal zone, and this can give rise to a splenic marginal zone lymphoma (SMZL). Early on, these show expansion of the marginal zone areas (D). Advanced cases show marked splenomegaly with miliary nodular structures replacing the spleen (E). There is marked expansile nodular replacement of the entire white pulp (F) with expression of IgD (G), a feature more common in SMZL compared to NMZL.

causal relationship has not yet been demonstrated. Chronic antigen stimulation is critical to both the development of a MALT lymphoma and the maintenance of the neoplastic state. Indeed, in some cases, antibiotic therapy and the eradication of *Helicobacter pylori* have led to the spontaneous remission of gastric MALT lymphoma in cases lacking genetic aberrations.

Immunophenotype MALT lymphomas are positive for B-cell-associated antigens CD19, CD20, and CD22, but are negative for CD5 and CD10. The absence of cyclin D1 is useful in ruling out MCL, especially in intestinal disease. Rare cases of MALT lymphoma have been reported to be CD5$^+$, and in some but not all instances, this has been associated with more aggressive disease. The clinical significance of increased transformed cells is still uncertain, and no formal grading system exists for MALT lymphoma. The putative cell of origin of MALT lymphoma is a postgerminal center B-cell.

MALT lymphomas also have several recurring cytogenetic abnormalities, including t(11;18)(q21;q21), t(1;14)(p22;q32), t(14;18)(q32;q21), t(3;14)(q27;q32), and t(3;14)(p14.1;q32), which are observed with variable frequency, often depending upon the anatomic site. Although several genes are involved in these translocations, at least three of them, t(11;18), t(1;14), and t(14;18), share a common pathway, leading to the activation of NF-κB and its downstream targets. By genome-wide DNA profiling integrated with GEP, differences were detected among the three different main types of marginal zone lymphomas, lending support to the current WHO classification that separates these three entities.[15]

Nodal Marginal-Zone B-Cell Lymphoma

Nodal marginal zone lymphoma (NMZL) is a primary nodal disease that resembles other marginal zone lymphomas, extranodal or splenic types. These patients often present with bone marrow involvement and tend to have a more aggressive clinical course than those with extranodal MALT. The neoplastic proliferation is polymorphous and composed of monocytoid B cells, plasmacytoid cells, with interspersed large blast-like cells. There is an expansion of the marginal-zone area, often with preservation of the nodal architecture (see Fig. 78.5C). The mantle zone may be intact, attenuated, or effaced. The immunophenotype is similar to other MZL, that is, CD20$^+$, CD10$^-$, CD5$^-$, with variable expression of IgD (weak to negative). Because there are no precise immunophenotypic or genotypic markers of NMZL, the diagnosis is sometimes one of exclusion. The differential diagnosis with LPL may be problematic; however, the MYD88 (L265P) somatic mutation is detected infrequently in MZL lymphomas and its presence should raise the possibility of LPL. More stringent criteria are needed to separate these two entities. A variant of nodal MZL occurs in children; these cases show a striking male predominance; present with localized disease, exhibiting a morphologic pattern; and can be managed with local therapies.

Splenic Marginal-Zone Lymphoma

Splenic marginal-zone lymphoma (SMZL) presents in adults and is slightly more frequent in females than males. The clinical presentation is splenomegaly, usually without peripheral lymphadenopathy. The majority of patients have marrow involvement, but there is usually only a modest lymphocytosis, with elevations in the lymphocyte count usually less than that seen in CLL. Some evidence of plasmacytoid differentiation may be seen, and patients may have a small M component. The abundant pale cytoplasm evident in tissue sections may also be seen in blood smears. The course is indolent, and splenectomy may be followed by a prolonged remission.

Histologically, the spleen shows expansion of the white pulp, but usually some infiltration of the red pulp is also present (see Fig. 78.5D).

A characteristic biphasic pattern in the neoplastic white pulp has been described, with the neoplastic cells surrounding regressed follicles. The immunophenotype of these cells resembles that of other marginal-zone B-cell lymphomas; however, IgD expression is more frequently observed. Progression to DLBCL can be seen.

Although the molecular pathogenesis of SMZL has not been fully delineated, a frequent cytogenetic alteration involving deletions of the region 7q(22-32) has been reported.[16] Mutations in *NOTCH2* are the most common event, but other genes in the NOTCH pathway may be targeted. Many of the affected genes appear to play a role in marginal zone B-cell development. The differential diagnosis of SMZL includes other unspecified B-cell lymphomas of the spleen, including splenic lymphoma with villous lymphocytes (SLVL), and hairy cell variant. The latter have been grouped together under splenic B-cell lymphoma/leukemia unclassifiable, and the interrelationship among these disorders is not fully resolved.

Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

DLBCL is one of the more common subtypes of non-Hodgkin lymphoma, representing up to 40% of cases. It has an aggressive natural history but responds well to chemotherapy. The complete remission rate with modern regimens is 75% to 80%, with long-term disease-free survival approaching 50% or more in most series. This lymphoma may present in lymph nodes or in extranodal sites. Frequent extranodal sites of involvement include bone, skin, thyroid, GI tract, and lung.

DLBCL represents one of the most heterogeneous categories in the WHO, and attempts to identify prognostic groups based on morphology and phenotype have shown limited usefulness and reproducibility (see box on Varied Basis for the Recognition of Diverse Entities). To address these issues, DLBCLs were among the first cases to be analyzed by complementary DNA (cDNA) array technology, and more recently also by genome-wide analysis. By GEP, three groups were identified based on the differential expression of a large set of genes, namely germinal center-like group (GCB), activated B-cell–like group (ABC), and primary mediastinal (thymic) large B-cell lymphoma (PMBL). PMBL is now recognized as a separate entity, and adaptations in GEP now allow profiling of formalin-fixed paraffin-embedded (FFPE) biopsies.[17] The ABC subtype frequently exhibits mutations in the BCR-signaling and NF-κB pathways providing new insight in the pathogenesis of DLBCL and new potential therapeutic targets.[18] Recurrent mutations in the GCB type of DLBCL appear to target histone-modifying genes.[19] Somatic mutations in *EZH2* also have been identified in FL, another tumor of germinal center derivation.

VARIED BASIS FOR THE RECOGNITION OF DIVERSE ENTITIES AMONG AGGRESSIVE B-CELL NEOPLASMS

- Cell of origin, in part as determined by gene expression profiling
  Activated B cell versus germinal center B cell
  Thymic B cell of PMBL
- Clinical factors
  Anatomic site, e.g., CNS, mediastinum, intravascular
  Advanced age, background of chronic inflammation
- Etiologic factors
  EBV, HHV-8
- Molecular pathogenesis
  ALK, BCL2, BCL6, C-MYC, MYD88 (translocations, amplification, mutation)

CNS, Central nervous system; *EBV*, Epstein–Barr virus; *HHV-8*, Human Herpesvirus-8; *PMBL*, Primary mediastinal large B-cell lymphoma.

DLBCLs are composed of large, transformed lymphoid cells with nuclei at least twice the size of a small lymphocyte (Fig. 78.6). The nuclei generally have vesicular chromatin, prominent nucleoli, and basophilic cytoplasm, resembling the centroblasts of the normal germinal center. The immunoblastic variant is characterized by cells with prominent central nucleoli and abundant deeply staining cytoplasm. Although there is no absolute correlation between morphology and GEP, the majority of centroblastic DLBCL falls into the GCB group, and the majority of immunoblastic fall into the ABC group.

Algorithms based on immunophenotype have been proposed as surrogates for cDNA microarray using CD10/BCL6 positivity for GCB and MUM1/IRF-4 for ABC with the addition of BCL2 in combination with IPI and may improve the stratification of DLBCL. Because of emerging differences in the treatment of GCB versus ABC (or non-GCB) DLBCL, it is recommended to include the subtype by

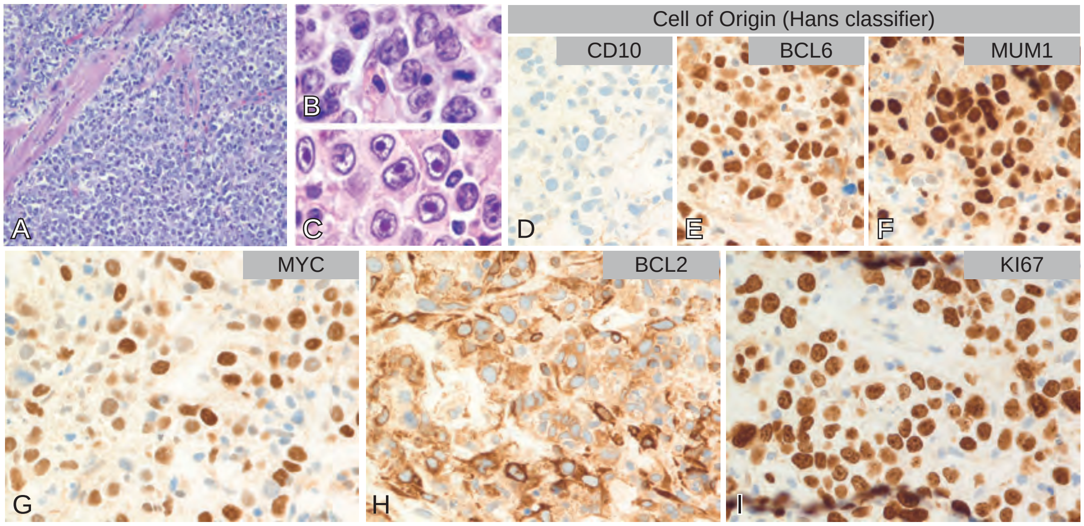

Figure 78.6 DIFFUSE LARGE B-CELL LYMPHOMA. The low-power illustration demonstrates the diffuse nature of the process (A). At high power (B,C), there are sheets of large cells. Those with a vesicular nuclear chromatin and variable numbers of nucleoli along the nuclear membrane are referred to as centroblasts (B) while cases with prominent central nucleoli are referred to as immunoblasts (C). The three markers used to assign cell of origin include CD10 (D), BCL6 (E), and MUM1 (F). This case corresponds to CD10-, BCL6+, MUM1+, non-germinal center phenotype. Additional prognostic markers include MYC (G), BCL2 (H), and KI67 (I). This case expresses 50% MYC (>40% considered positive), weak uniform BCL2 (>50% considered positive), and high proliferation of 90%. Based on the profile, this is a non-GCB, double-expressor of MYC and BCL2.

integrating GEP and/or IHC results in the report with clarification of the method used and the type of algorithm. As noted, newer GEP methods may be applicable to FFPE material.[17]

Diffuse Large B-Cell Lymphomas, Other Variants, and Subtypes

The spectrum of aggressive B-cell lymphomas has broadened in recent years, incorporating new entities based on unique clinical features such as age or anatomic site, viral pathogenesis (EBV, human herpesvirus [HHV]-8), or distinctive pathologic features.[20] *T-cell/histiocyte-rich large B-cell lymphoma (THRLBCL)* has distinctive morphologic and clinical features. It is associated with aggressive clinical behavior and often presents with advanced stage and bone marrow involvement. The relevance of the microenvironment and recruitment mechanism of the inflammatory cells, which are the main histologic component, has been the focus of recent studies.[21]

The WHO classification recognizes that some lymphomas arising in certain anatomic sites may have distinctive features both clinically and biologically. Among these are *primary DLBCL of the central nervous system (CNS)* and *DLBCL of the testis*. DLBCLs in these sanctuary sites differ at the genomic level from the usual nodal DLBCL. Both primary CNS DLBCL and intraocular large B-cell lymphomas commonly have mutations in MYD88.

Primary cutaneous DLBCL, leg type, has a GEP resembling the ABC type of DLBCL, presents most often in older adult females, and generally has an aggressive clinical course. As with nodal DLBCL, BCL2 expression is an adverse prognostic factor.

EBV-positive DLBCL was a provisional entity in the 2008 WHO classification and was accepted as a definitive entity in WHO 2017.[3] It was first recognized in the older adult.[22] More recent studies have shown a wider age distribution. Decreased immune surveillance in the older adult or a tolerogenic immune microenvironment may facilitate tumor development.[23] The morphologic spectrum is broad, but most cases have a prominent inflammatory background. The prognosis in the older adult is poor, but younger patients have a good outcome. EBV-positive DLBCL should be distinguished from EBV$^+$ mucocutaneous ulcer, which affects mainly cutaneous sites, and often has a self-limited clinical course. These lesions arise in a setting of decreased immune surveillance, most often in the elderly, and frequently with iatrogenic immune suppression.

Lymphomatoid granulomatosis is an EBV$^+$ B-cell lymphoproliferative disorder (LPD) associated with an inflammatory background rich in T cells. The lung is nearly always involved, with skin, kidney, liver, and brain being frequently affected as well. *DLBCL associated with chronic inflammation* was first described in association with chronic pyothorax but now has been associated with EBV-driven large B-cell proliferations in diverse clinical settings and is usually associated with a confined anatomic space and a background of chronic inflammation. These cases appear to have a good prognosis if successfully resected.

There are several LPDs associated with HHV-8/Kaposi sarcoma-associated herpesvirus (KSHV). These include *primary effusion lymphoma (PEL)* and *multicentric Castleman disease (MCD)*. The cells of PEL are usually coinfected with EBV, and the disease is most often diagnosed in the setting of human immunodeficiency virus (HIV) infection and immunosuppression. While pleural or peritoneal effusions are most common, extracavitary PEL can present as a tumor mass, usually in extranodal sites. PEL has a phenotype resembling that of terminally differentiated B-cells, i.e., plasmablastic (Fig. 78.7).

Two other lymphomas with a plasmablastic phenotype include *plasmablastic lymphoma (PBL)* and *anaplastic lymphoma kinase (ALK)-positive large B-cell lymphoma*. PBL is usually positive for EBV, most often extranodal, and associated with immunosuppression from either HIV infection or advanced age. Recent studies have identified a high incidence of *MYC* translocation in PBL.[24] ALK-positive large B-cell lymphomas show overexpression of ALK, usually as a consequence of translocation involving a partner gene other than *NPM1*. They mainly affect older individuals but can occur at any age. Interestingly, IgA is often expressed.

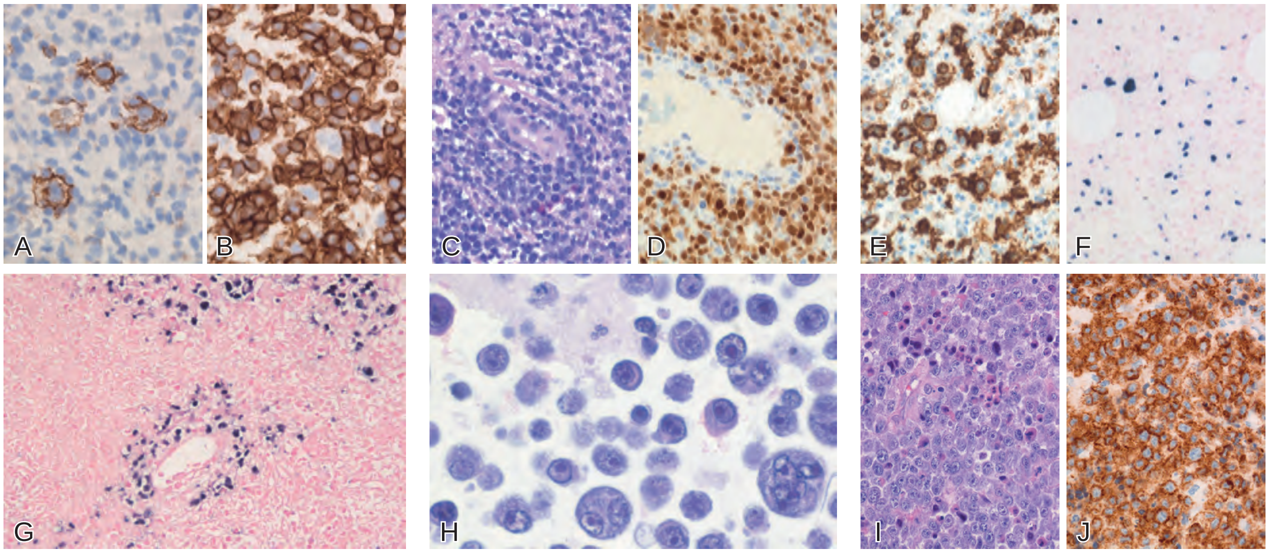

Figure 78.7 DIFFUSE LARGE B-CELL LYMPHOMA, VARIANTS, AND SUBTYPES. T-cell/histiocyte–rich large B-cell lymphoma is illustrated in (A, B), where a CD20 immunostain (A) identifies scattered large B cells, which are associated with a prominent background of small reactive T cells (CD3; B). Sometimes there are numerous histiocytes in the background or an admixture of reactive T cells and histiocytes. Primary diffuse large B-cell lymphoma (DLBCL) of the central nervous system usually shows a perivascular distribution (C) with frequent non-germinal center B-cell phenotype with expression of MUM1 (D). Epstein-Barr virus (EBV)–positive DLBCL can have variable morphologic features. The illustrated case is monomorphic and composed of large cells, which are positive for CD20 (E) and EBV-encoded RNA (EBER) (F). Note large Hodgkin-like EBER+ cells with a spectrum of size in positive cells. Lymphomatoid granulomatosis also has a perivascular distribution and is composed of a mix of malignant large EBV-positive B cells (G) and reactive T cells (not shown). Primary effusion lymphoma is usually diagnosed from cytologic preparations (H) and by flow cytometric and molecular techniques. Although the tumor cells do not generally form masses, extracavitary primary effusion lymphoma can present as a tumor mass, usually in extranodal sites. ALK$^+$ large B-cell lymphomas are rare and exhibit plasmablastic morphology (I) with ALK positivity as a consequence of a translocation of *ALK* (J). *ALK*, Anaplastic Lymphoma kinase; *RNA*, ribonucleic acid.

Intravascular Large B-Cell Lymphoma

Intravascular large B-cell lymphoma is a rare form of DLBCL characterized by the presence of lymphoma cells only in the lumens of small vessels, particularly capillaries (Fig. 78.8A). The neoplastic cells express B-cell related antigens including CD19 and CD20. The tumor cells are large, with vesicular nuclei and prominent nucleoli, resembling centroblasts or immunoblasts. Lymph node involvement is rare, and the tumor presents in extranodal sites, most readily diagnosed in the skin or bone marrow biopsy. Neurologic symptoms associated with the plugging of small vessels in the CNS are common. The disease is often not diagnosed until autopsy because of the lack of definitive radiologic or clinical evidence of disease and diverse symptomatology.

Primary Mediastinal (Thymic) Large B-Cell Lymphoma

PMBL has emerged in recent years as a distinct clinicopathologic entity, typically arising in young women, with a peak incidence in the fourth decade. Patients present with a mediastinal mass, with frequent superior vena cava syndrome. Regional lymph nodes may be involved but spread to distant nodal sites is uncommon. Frequent extranodal sites of involvement, particularly at relapse, include the liver, kidneys, adrenal glands, ovaries, GI tract, and CNS.

Histologically, PMBL is characterized by fine compartmentalizing sclerosis and large lymphoid cells with abundant pale cytoplasm (see Fig. 78.8C). An origin from medullary thymic B cells is proposed. The cells express CD20 and CD79a but do not express surface Ig. Recently, expression of the *MAL* gene has been detected in PMBL and not in other DLBCLs.[25] PMBL usually lack rearrangement for *BCL2*, *BCL6*; however, *REL* amplification is a common feature. A common cytogenetic abnormality seen in approximately 50% of cases includes gains in 9p, which may be associated with amplification of *JAK2* and *PDL1*/*PDL2* as well as translocations involving MHC class II transactivator (*CIITA*). Recently, GEP studies have found that PMBL bears a distinct molecular signature that differs from that of other DLBCLs and shares features of CHL; however, the same signature is not restricted to mediastinal sites since it can also be detected in other DLBCLs not otherwise specified (NOS) at nonmediastinal sites.

B-Cell Lymphoma, Unclassifiable, With Features Intermediate Between Diffuse Large B-Cell Lymphoma and Classic Hodgkin Lymphoma

This lymphoma is sometimes referred to as mediastinal gray zone lymphoma since the mediastinum is the most common site of presentation. A close relationship between PMBL and CHL was supported by GEP. TRAF1 expression and c-REL amplification were also seen in both types of neoplasms and could be detected with suitable immunohistochemical studies.

Gray zone lymphomas are more common in males than females, present with bulky mediastinal masses, and appear to have a more aggressive clinical course than PMBL or CHL. A recent study using methylation profiling identified gray zone lymphomas as having a signature distinct from both CHL and PMBL.[26] However, by fluorescence in situ hybridization, gray zone lymphomas, PBMCL and CHL share a number of common cytogenetic aberrations including gains at 2p16.1 (*REL*/*BCL11A* locus), 9p24.1 (*JAK2*/*PDL2*), and rearrangements of 16p13.13 (*CIITA*). It is not clear how these patients should be approached therapeutically, but they appear to benefit from combined modality therapy (systemic chemotherapy and radiation).

Burkitt Lymphoma

Burkitt lymphoma (BL) is most common in children and accounts for up to one-third of all pediatric lymphomas in the United States. It is the most rapidly growing of all lymphomas, with 100% of the cells in the cell cycle at any time. It usually presents in extranodal sites. In nonendemic regions, such as the United States, frequent sites of presentation are the ileocecal region, ovaries, kidneys, or breasts. Jaw presentations, as well as involvement of other facial bones, are common in African or endemic cases and are seen occasionally in nonendemic regions. Bone marrow involvement is a poor prognostic sign.

BL is one of the more common tumors associated with HIV. It can present at any time during the clinical course. In some patients with HIV infection, BL may be the initial acquired immunodeficiency syndrome-defining illness.

The pathogenesis of BL is related to the translocations involving the *MYC* oncogene, which are seen in virtually 100% of cases and often constitute the sole karyotypic abnormality. Most cases involve the IG heavy-chain gene on chromosome 14 and less frequently the light-chain genes on chromosomes 2 and 22. In endemic BL, genomic instability is thought to be promoted by *Plasmodium* infection.[27] EBV is closely linked to BL in endemic regions but is less frequently seen (15% to 20%) in sporadic cases. In other regions, characterized by low socioeconomic status and EBV infection at an early age, BL is often EBV$^+$, in the range of 50% to 70%. These data support the concept that the EBV is a cofactor for the development of BL. Cytologically, BL is monomorphic (Fig. 78.9). The cells are medium in size with round nuclei, moderately clumped chromatin, and multiple (2 to 5) basophilic nucleoli. The cytoplasm is deeply basophilic and moderately abundant. These cells contain cytoplasmic lipid vacuoles, which are probably a manifestation of the high rate of proliferation and high rate of spontaneous cell death. The starry sky pattern characteristic of BL is a manifestation of the numerous benign macrophages that have ingested karyorrhectic or apoptotic tumor cells.

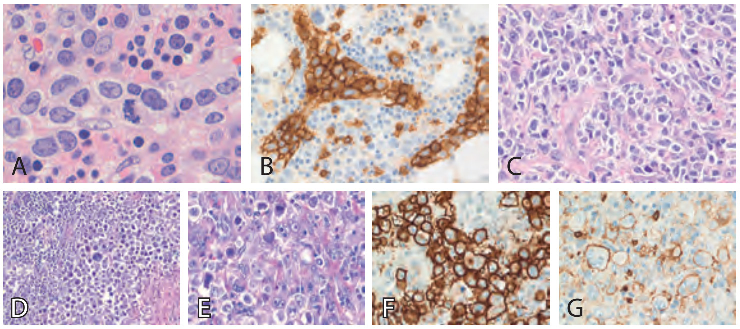

Figure 78.8 DIFFUSE LARGE B-CELL LYMPHOMA VARIANTS (INTRAVASCULAR, MEDIASTINAL, GRAY ZONE). In intravascular lymphoma, also known as angiotropic lymphoma, the large B cells are confined to the lumens of small vessels (A) and are sometimes very difficult to see in bone marrow biopsies and better seen on the CD20 stain (B). Paradoxically, they do not spread to the blood. Primary mediastinal (thymic) large B-cell lymphoma typically shows large B cells in a finely sclerotic background (C). So-called "gray zone lymphoma" has features intermediate between large B-cell lymphoma and Hodgkin lymphoma. In the case illustrated (D–G), the male patient presented with a mediastinal mass showing sheet-like DLBCL type areas (D) with other pleomorphic Hodgkin-like areas (E). The former areas are strongly CD20$^+$ (F) while the cHL-like areas express variable weak-negative CD20 (G). All cells were variably positive for CD30 in this case.

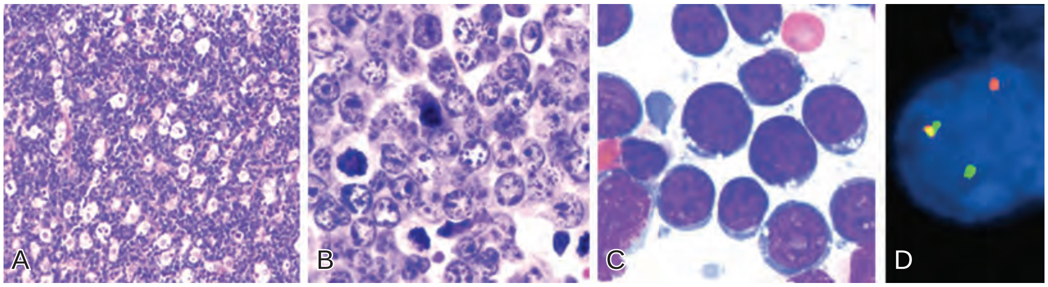

Figure 78.9 BURKITT LYMPHOMA. At low power, Burkitt lymphoma gives a classic "starry sky" appearance because of numerous histiocytes or tingible body macrophages with clear cytoplasm *(stars)*, in a background of darkly stained tumor cells (A). At high power, the cells exhibit a very high mitotic rate and are intermediate in size with finely clumped nuclear chromatin (B). On a Wright-stained touch preparation or in the blood or bone marrow aspirate, the cells also have a characteristic appearance with deep blue cytoplasm typically with vacuoles (C). Fluorescence in situ hybridization with a probe that spans *MYC* will show a break-apart signal (D) indicating that *MYC* has translocated to a partner chromosome.

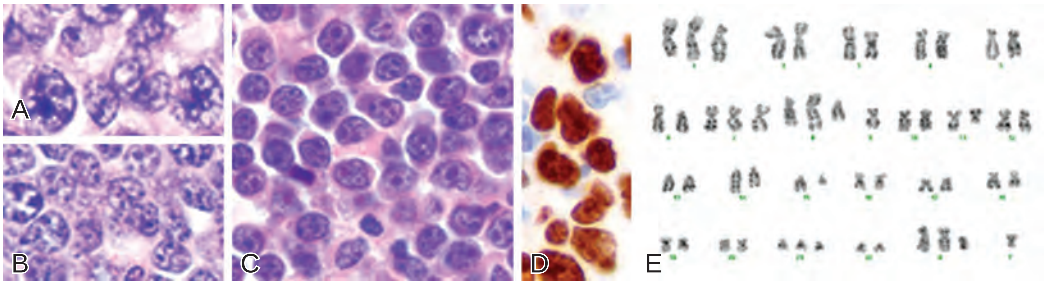

Figure 78.10 HIGH-GRADE B-CELL LYMPHOMA WITH *MYC* AND *BCL2* AND/OR *BCL6* REARRANGEMENTS. Examples of diffuse large B-cell lymphoma (DLBCL) (A) and Burkitt lymphoma (BL) (B) are for comparison. In (C), the lymphoma cells are intermediate in size and not as large as the DLBCL but without the typical characteristics of BL cells. The cells had a high Ki67 rate (D) and a B-cell phenotype with CD10 and BCL2 expression (not shown). The karyotype had a t(14;18) as in follicular lymphoma, MYC translocation as in BL, but was complex with multiple aberrations. The karyotype (E) was as follows: 51,XY,+X,+1,dup(1)(q32q44),der(1)del(1)(p21p36.3)dup(1)(q32q44),t(6;8)(p21.1;q24.1),+7,+del(?8) (p11.2p23),der(8)i(8)(q10)t(8;11)(q24.1;q13),9,der(11)t(8;11)(q24.1;q13), t(14;15)(q32;q15), t(14;18)(q32;q21.3),+21,+mar[13]/46,XY[1]. *(The karyotype was kindly provided by Dr. Yanming Zhan of Northwestern University.)*

BL has a mature B cell phenotype. The cells express CD19, CD20, CD22, CD79a, and monoclonal surface Ig, nearly always IgM. CD10 is positive in nearly all cases, and CD5, CD23, and BCL2 are consistently negative.

High-Grade B-Cell Lymphoma, with *MYC* and *BCL2* and/or *BCL6* Rearrangements

Historically, it has been difficult for pathologists to distinguish some DLBCL with a very high growth fraction from BL with atypical cytology. In addition, there are cases that carry a *C-MYC* translocation but carry additional cytogenetic abnormalities, most often involving *BCL2* or *BCL6*. These double-hit and triple-hit lymphomas have a very aggressive clinical course and have been separated out in the revised 2017 WHO classification (Fig. 78.10).[3] The clinical impact of *MYC* overexpression in DLBCL has not been fully resolved; in some series, it has been associated with a more aggressive clinical course. For the time being, an otherwise typical DLBCL with a *C-MYC* translocation should still be classified as DLBCL. Cases of BL with atypical cytologic features are retained under the heading of BL and have a better prognosis when treated appropriately.

T-CELL AND NATURAL KILLER-CELL LYMPHOMAS

Overview of the Classification of T-Cell Neoplasms

Although the definition of precursor T-cell or lymphoblastic neoplasms is straightforward, the classification of peripheral T-cell lymphomas has been controversial. These are uncommon, representing less than 15% of all non-Hodgkin lymphomas. Most previously published classification schemes for the malignant lymphomas in the United States or Europe have been based on B-cell malignancies, as these are far more common than their T-cell counterparts. T-cell and NK-cell lymphomas show significant variation in incidence in different geographic regions and racial populations.

The classification of T-cell and NK-cell neoplasms proposed by the WHO emphasizes a multiparameter approach, integrating morphologic, immunophenotypic, genetic, and clinical features. Clinical features play particular importance in the subclassification of these tumors, in part caused by the lack of specificity of other parameters (see box on Natural Killer and T-Cell Subsets).

NATURAL KILLER AND T-CELL SUBSETS AND THE CLASSIFICATION OF PERIPHERAL T-CELL AND NATURAL KILLER-CELL NEOPLASMS

Innate Immune System	Adaptive Immune System
Does not require antigen sensitization	Characterized by specificity and memory
NK-cells, NK/T-cells, gamma-delta T-cells	Effector and memory T-cells
Cell-mediated cytotoxicity	Act principally through cytokines and chemokines
Mainly cutaneous and other extranodal sites	Mainly nodal lymphomas
Children and adults	More often in adults

NK, Natural killer.

In contrast to B-cell lymphomas, specific immunophenotypic profiles are not associated with most T-cell lymphoma subtypes. Although certain antigens are commonly associated with specific disease entities, these associations are not entirely disease-specific. Presently, specific genetic features have not been identified for many of the T-cell and NK-cell neoplasms, although there are few exceptions.

Angioimmunoblastic T-Cell Lymphoma

Angioimmunoblastic T-cell lymphoma (AITL) was initially proposed as an abnormal immune reaction or form of atypical lymphoid hyperplasia with a high risk of progression to malignant lymphoma. Because the majority of cases show clonal rearrangements of T-cell receptor genes, it is now regarded as a variant of T-cell lymphoma. The median survival is generally less than 5 years.

AITL presents in adults; most patients have generalized lymphadenopathy, hepatosplenomegaly, skin rash, and prominent constitutional symptoms. There is usually polyclonal hypergammaglobulinemia and other hematologic abnormalities such as Coombs-positive hemolytic anemia. Rituximab has been used in some recent clinical trials in an attempt to control some of the effects of B-cell hyperactivity in this disease. Patients may also show evidence of immunodeficiency with recurrent opportunistic infections that may ultimately lead to their demise.

The nodal architecture is generally effaced, but peripheral sinuses are often open and even dilated. At low power, there is usually a striking proliferation of high endothelial venules (HEV) with prominent arborization (Fig. 78.11A). Follicles are typically regressed, but there is a proliferation of dendritic cells around HEV. The atypical T-cells have clear cytoplasm and are associated with small lymphocytes, immunoblasts, plasma cells, and histiocytes. The abnormal T-cells are usually positive for CD3, CD4, CD10, and CD279 (PD-1), a phenotype characteristic of follicular T-helper cells. This relationship is also confirmed by recent GEP data. CXC-chemokine ligand 13, a chemokine involved in B-cell trafficking into the germinal centers, is also expressed in AITL.

EBV$^+$ large B-cell blasts, sometimes with Reed–Sternberg (RS) like features, are nearly always present in the background, and progression to EBV-positive DLBCL has been reported in rare cases. Atypical B-cell proliferations that are negative for EBV also occur, presumably related to the T-helper follicular function of the neoplastic cells in promoting the activation and migration of bystander B cells. However, the exact role of EBV in AITL remains uncertain. Recently, recurrent mutations have been reported in AITL; these include mutations in *IDH2*, *TET2*, and *RHOA*.

The biologic spectrum of AITL is greater than previously thought and other entities related to follicular T-helper cells are considered within the same group. The updated version of the WHO 2017 classification recognizes AITL, follicular T-cell lymphoma, and nodal peripheral T-cell lymphoma of T-follicular helper phenotype, all within the umbrella of nodal T-cell neoplasm of T-helper follicular origin given their similar underlying molecular alterations.[3]

Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma (ATL) is a distinct clinicopathologic entity associated with the retrovirus human T-lymphotropic virus-1 (HTLV-1), which is found clonally integrated into the T cells. HTLV-1 infection is endemic in Southwestern Japan and in the Caribbean basin. The disease has a long latency, and affected individuals are usually exposed to the virus very early in life. The virus may be transmitted in breast milk, and through exposure to blood and blood products. The cumulative incidence of ATL is estimated to be 2.5% among HTLV-1 carriers.

The median age of affected individuals is 45 years. Patients may present with leukemia or with generalized lymphadenopathy. Other clinical findings include lymphadenopathy, hepatosplenomegaly, lytic bone lesions, and hypercalcemia. Cutaneous involvement is seen in the majority of patients. The acute form of the disease is associated with a poor prognosis and a median survival of less than 2 years. Complete remissions may be obtained but the relapse rate is nearly 100%.

Chronic and smoldering forms of the disease are seen less commonly and are associated with minimal lymphadenopathy. The predominant clinical manifestation is skin rash, with only small numbers of atypical cells in the peripheral blood.

The cytologic spectrum of ATL is extremely diverse. The cells are often markedly polylobated and have been referred to as flower cells. (see Fig. 78.11B). Peripheral blood involvement is very common and occurs often in the absence of bone marrow disease. Immunophenotypically, the neoplastic cells are positive for mature T-cell antigens, such as CD2, CD3, and CD5; they are typically CD4/CD25$^+$, a phenotype that resembles regulatory T (Treg) cells. Some cases express FoxP3, but usually in a minority of tumor cells. The function of the tumor cells as Treg cells may correlate with the associated immunodeficiency.

Peripheral T-Cell Lymphomas, Not Otherwise Specified

PTCL, NOS is a diagnosis of exclusion and is admittedly a heterogeneous category with most cases being nodal in origin. Therefore, the cytologic spectrum is very broad (see Fig. 78.11C).[28] An inflammatory background is frequent, consisting of eosinophils, plasma cells, and histiocytes. If the epithelioid histiocytes are numerous and clustered, the neoplasm fulfills the criteria for the *lymphoepithelioid cell variant* of PTCL.

Clinically, PTCL, NOS most often presents in adults with generalized lymphadenopathy, hepatosplenomegaly, and frequent bone marrow involvement. Constitutional symptoms, including fever and night sweats, are common, as is pruritus. The clinical course is aggressive, although complete remissions may be obtained with

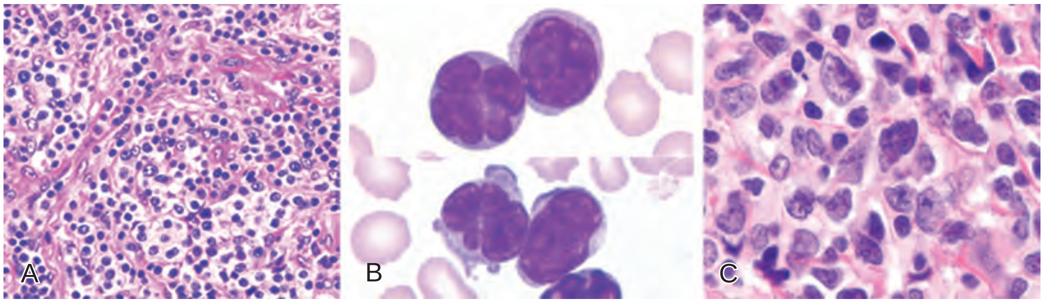

Figure 78.11 PERIPHERAL T-CELL LYMPHOMAS. In angioimmunoblastic T-cell lymphoma, the lymph node shows effacement with an arborizing vascular proliferation of postcapillary venules and clustered large cells with clear cytoplasm in the background of plasma cells, immunoblasts, and small lymphocytes (A). The peripheral blood in adult T-cell leukemia/lymphoma has classic "flower-cells" (B). Peripheral T-cell lymphoma, not otherwise specified is heterogeneous, but typically there is a mixture of small and large neoplastic T cells (C).

combination chemotherapy frequently including etoposide and brentuximab (anti-CD30 antibody conjugate). However, the relapse rate is higher than in aggressive B-cell lymphomas, including DLBCL.

PTCL, NOS, as defined in the WHO classification, remains heterogeneous. It is likely that individual clinicopathologic entities will be delineated in the future from this broad group of malignancies. Delineated separately from this category are tumors with a T-follicular helper (TFH) cell phenotype including the follicular T-cell lymphoma. Most cases have a mature T-cell phenotype and express one of the major subset antigens: CD4 more frequently than CD8 with loss of one of the pan T-cell antigens (CD3, CD5, CD2, or CD7) seen in 75% of cases, with CD7 most frequently being absent. GEP studies have shown some cases with a profile resembling AITL. Cases with a high proliferation signature appear to have a more aggressive clinical course, but GEP has not led to the delineation of distinctive subtypes as independent entities.

Anaplastic Large Cell Lymphoma, Anaplastic Lymphoma Kinase-Positive

Anaplastic large cell lymphoma (ALCL) is characterized by pleomorphic or monomorphic cells, which have a propensity to invade lymphoid sinuses (Fig. 78.12). Because of the sinusoidal location of the tumor cells and their lobulated nuclear appearance, this disease when first observed was suspected to be of histiocytic origin. A consistent feature is the strong expression of CD30 antigen, a diagnostic hallmark. However, CD30 expression is not specific for ALCL and can be seen in a variety of conditions, including, of course, CHL. Systemic ALCL is associated with a characteristic chromosomal translocation, t(2;5)(p23;q35) involving *NPM/ALK* genes, respectively. A number of variant translocations have been identified that involve partners other than *NPM*. All lead to overexpression of *ALK*, although the cellular distribution of ALK varies according to the gene partner.

The cells of classic ALCL have large, often lobulated nuclei with small basophilic nucleoli, so-called hallmark cells. The cytoplasm is usually abundant, amphophilic, and there are distinct cytoplasmic borders. A prominent Golgi region is generally visible. Small cell and lymphohistiocytic variants constitute part of the entity and appear to be associated with a more aggressive clinical course.

The cells exhibit an aberrant phenotype with loss of many of the T-cell-associated antigens. Both CD3 and CD5 are negative in greater than 50% of cases. CD2 and CD4 are positive in the majority of cases. CD8 is usually negative. ALCL cells, despite the $CD4^+/CD8^-$ phenotype, exhibit positivity for the cytotoxic associated antigens TIA-1, granzyme B, and perforin. In addition, clusterin is generally present in ALCL and represents another useful diagnostic marker. By molecular studies, in most of the cases, a clonal T-cell receptor rearrangement is found, supporting T-cell origin despite negative CD3.

ALK-positive ALCL is most common in children with a marked male predominance and incidence of ALK positivity drops sharply in young adults and older. Although most patients present with nodal disease, a high incidence of extranodal involvement has been reported (involving skin, bone, and soft tissue). Approximately 75% of cases present with advanced-stage and systemic symptoms. Although these lymphomas have an aggressive natural clinical history, they respond well to chemotherapy. Overall survival and disease-free survival are significantly better among ALK^+ versus ALK^- cases. Both ALK^+ and ALK^- ALCL have a better prognosis than other PTCLs, with a plateau in the survival curve seen in both groups.[29]

Anaplastic Large Cell Lymphoma, ALK-Negative

It has been controversial whether ALCL negative for ALK is a separate entity or part of the spectrum of PTCL, NOS. Part of the controversy relates to the lack of absolute criteria to recognize these cases. They should be morphologically (i.e., sinusoidal and cohesive growth pattern, presence of hallmark cells) and phenotypically similar to ALK^+ ALCL, with strong CD30 expression. A cytotoxic phenotype is common but is not essential. They occur in an older age group than the ALK^+ and, as noted earlier, appear to have a better prognosis than other PTCL, NOS. Recent molecular/cytogenetic studies have identified candidate genes *TP63* and *DUSP22*; the latter is associated with a more favorable outcome. Both ALK^+ and ALK^- ALCL appear to share activation of the JAK/STAT pathway.[30]

Primary Cutaneous Anaplastic Large Cell Lymphoma

The primary cutaneous form of ALCL is closely related to lymphomatoid papulosis (LYP) and differs clinically, immunophenotypically, and at the molecular level from the systemic form. LYP and cutaneous ALCL are part of the spectrum of $CD30^+$ cutaneous T-cell lymphoproliferative diseases. Small lesions are likely to regress. Patients with large tumor masses may develop disseminated disease with lymph node involvement. However, primary cutaneous ALCL is a more indolent disease than other T-cell lymphomas of the skin. Because the skin nodules may show spontaneous regression, usually a period of observation is warranted before the institution of any chemotherapy. Cutaneous ALCL is $CD30^+$ but ALK^-, lacking translocations involving the *ALK* gene. However, recent studies have identified rearrangements of *DUSP22* in a subset of cutaneous ALCL.

Mycosis Fungoides/Sézary Syndrome

Mycosis fungoides/Sézary syndrome (MF/SS) are now regarded as separate diseases but are closely related and often considered together from a clinical and biologic standpoint.[31] Both are primary cutaneous T-cell malignancies derived from mature CD4 positive skin-homing T cells. Skin involvement may be manifested as multiple cutaneous plaques or nodules. SS is characterized by erythroderma and a leukemic phase. Lymphadenopathy is usually not present at presentation

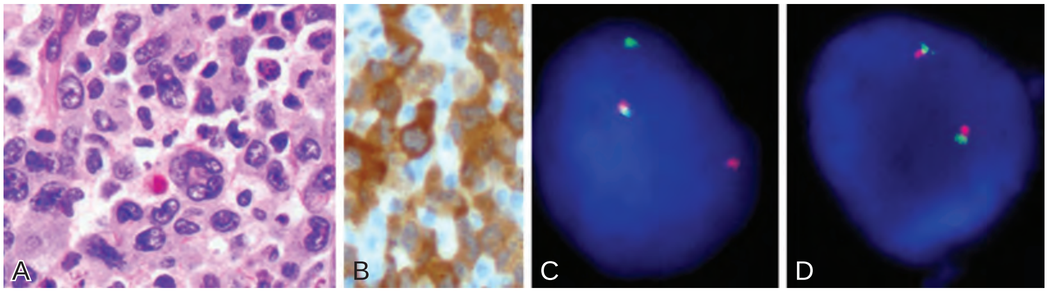

Figure 78.12 ANAPLASTIC LARGE CELL LYMPHOMA. Anaplastic large cell lymphoma can show a wide spectrum in cell size, and there is a small cell variant in addition to the more typical common form. The cells (A) include "wreath cells" *(center)* and "hallmark cells" *(bottom right)*. (B), The presence of ALK staining with nuclear and cytoplasmic localization *(right)* is associated with the t(2;5). A translocation of *ALK* can be identified with a break-apart probe that spans *ALK* but is split when *ALK* is translocated to one of a number of partners. A cell with a translocated *ALK* is pictured in (C) and a normal cell in (D). *ALK*, Anaplastic lymphoma kinase.

and, when identified, is associated with a poor prognosis. In early stages, enlarged lymph nodes may only show very minimal morphologic changes (Category I). If malignant cells are present in significant numbers and are associated with architectural effacement (Category II or III), the prognosis is significantly worse.

Cytologically, the small cells of MF demonstrate cerebriform nuclei with clumped chromatin, inconspicuous nucleoli, and sparse cytoplasm. Epidermotropism is usually a prominent feature (Fig. 78.13). SS presents with exfoliative erythroderma and circulating cerebriform lymphocytes known as Sézary cells. The typical phenotype is CD2$^+$, CD3$^+$, CD5$^+$, CD4$^+$, and CD8$^-$. However, CD8$^+$ variants of MF have been described and are more common in children. The absence of CD7 is a constant feature but may also be seen in reactive conditions and therefore is of limited diagnostic value. Aberrant expression of other T-cell antigens may be seen but mainly occurs in the advanced (tumor) stages. Inactivation of p16 (*CDKN2A*) and *PTEN* has been identified in some cases and may be associated with disease progression.

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma (SPTCL) usually presents with subcutaneous nodules, primarily affecting the extremities and trunk. The nodules range in size from 0.5 cm to several centimeters in diameter. In its early stages, the infiltrate may appear deceptively benign, and lesions are often misdiagnosed as panniculitis. However, histologic progression usually occurs and subsequent biopsies show more pronounced cytologic atypia, permitting the diagnosis of malignant lymphoma.

Atypical lymphoid cells rim individual fat cells. Admixed reactive histiocytes are frequently present, particularly in areas of fat infiltration and destruction. Vascular invasion may be seen in some cases, and necrosis and karyorrhexis are common (see Fig. 78.13C).

The neoplastic cells are CD8$^+$ T alpha-beta cells, with tumors composed of gamma-delta T-cells now included under primary cutaneous gamma-delta T-cell lymphomas. The cells display an activated cytotoxic immunophenotype (positive for TIA-1, granzyme-B, and perforin). These proteins may be responsible for the cellular destruction seen in these tumors.

A hemophagocytic syndrome is less often seen in SPTCL than in panniculitis-like tumors of gamma-delta T-cell derivation, but whenever seen, it is associated with an adverse prognosis.[32] Patients present with fever, pancytopenia, and hepatosplenomegaly. The cause of the hemophagocytic syndrome appears related to cytokine production by the malignant cells with recent evidence indicating germline mutations in the T-cell Ig mucin 3 (*TIM-3*) gene in many cases.[33]

Primary Cutaneous Gamma-Delta T-Cell Lymphoma

Primary cutaneous gamma-delta T-cell lymphoma is considered a distinct entity, which can involve the subcutis, the dermis, or with epidermal infiltration. These are clinically aggressive tumors. The cells have a cytotoxic phenotype, and like normal gamma delta T-cells, lack CD5, are positive for TCR-gamma, and express cytotoxic molecules. They may be CD8$^+$ or more often double negative for CD4 and CD8. It is important to rule out MF and LYP before rendering a diagnosis of primary cutaneous gamma-delta T-cell lymphoma since there are newly recognized forms of LYP that share morphologic and phenotypic features. While skin is the most common presenting site, lymphomas of gamma delta T-cell origin can present in other mainly extranodal sites. The cells are invariably EBV$^-$ and show clonal rearrangement of T-cell receptor genes.

Primary Cutaneous CD8$^+$ Aggressive Epidermotropic Cytotoxic T-Cell Lymphoma and Primary Cutaneous CD4$^+$ Small/Medium T-Cell Lymphoproliferative Disorder

Primary cutaneous CD8$^+$ aggressive epidermotropic cytotoxic T-cell lymphoma is an aggressive cutaneous neoplasm that shares many clinical features with primary cutaneous gamma delta T-cell lymphomas but is derived from cytotoxic alpha-beta T cells. As the term implies, the neoplastic cells show prominent epidermotropism.

Primary cutaneous CD4$^+$ small/medium T-cell LPD most often presents with localized skin lesions. It is associated with an excellent prognosis and requires only limited localized therapy unless multiple skin lesions are present. The term LPD rather than lymphoma is used, reflecting the indolent nature of the proliferation. The lesions are rich

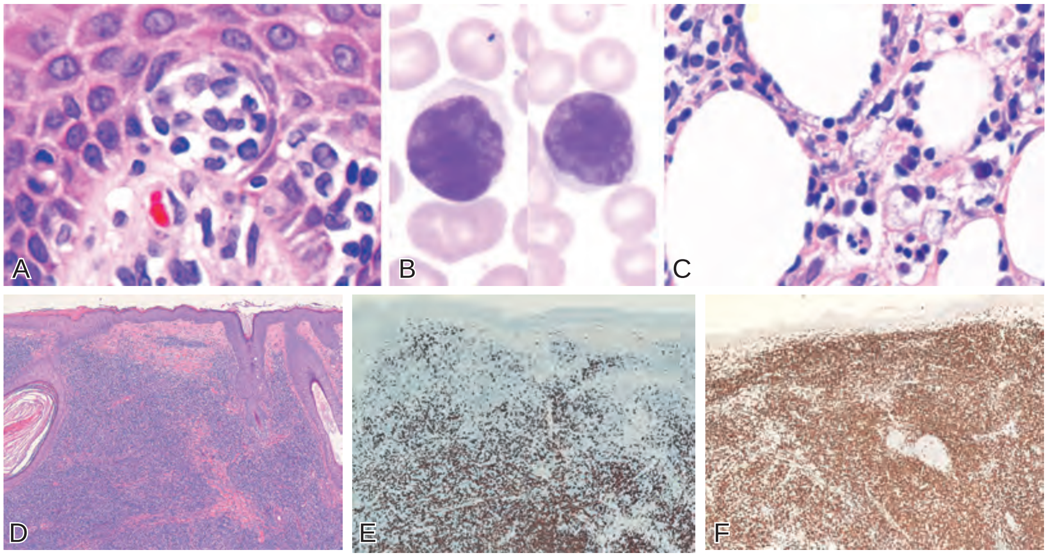

Figure 78.13 CUTANEOUS T-CELL LYMPHOMAS: MYCOSIS FUNGOIDES/SÉZARY SYNDROME AND SUBCUTANEOUS PANNICULITIS-LIKE T-CELL LYMPHOMA. In mycosis fungoides, there is a dermal infiltrate with some malignant T cells infiltrating into the epithelium (Pautrier microabscesses) (A). Sézary cells with convoluted nuclear folding are seen in (B). The peripheral nuclear outline is fairly rounded, but the internal nuclear detail shows complex nuclear folding giving rise to a convoluted and cerebriform look. A case of subcutaneous panniculitis-like T-cell lymphoma is illustrated and shows an abnormal lymphoid infiltrate in the subcutaneous fat (C). Fat necrosis is usually evident. Primary cutaneous small medium T-cell lymphoproliferative disorder is characterized by dense dermal infiltrate of small–medium sized lymphoid cells without epidermotropism (D). Numerous background CD20$^+$ B-cells (E) are noted besides CD3$^+$ T cells (F).

in B cells, and the proliferating T cells have a TFH phenotype, with clonality usually evident by molecular testing.

Enteropathy-Associated T-Cell Lymphoma

Two variants of enteropathy-associated T-cell lymphoma (EATL) were recognized in the WHO 2008, EATL Type I and Type II. The classic Type I form of EATL is associated with either overt or clinically silent gluten-sensitive enteropathy and is largely seen in patients of European extraction, whereas the Type II form has a more worldwide distribution. In recognition of its distinction from EATL Type I, the revised WHO classification designates these as "monomorphic epitheliotropic intestinal T-cell lymphoma." Patients usually present with abdominal symptoms, including pain, small bowel perforation, and associated peritonitis. The clinical course is aggressive, and most patients have multifocal intestinal disease.[28,34]

In EATL, Type I (Fig. 78.14A), the cytologic composition is somewhat varied; the neoplastic cells show prominent invasion of the mucosa and are cytotoxic T cells most often of alpha-beta origin. The cells also express the homing receptor CD103 (HML-1). Cells with anaplastic features positive for CD30 may be present. In EATL Type I, the adjacent small bowel usually shows villous atrophy associated with celiac disease. In EATL Type II, (now monomorphic epitheliotropic intestinal T-cell lymphoma), the infiltrate is monomorphic and composed of medium-sized cells with clear cytoplasm showing prominent epitheliotropism. They are CD8$^+$, CD56$^+$, and most often of gamma-delta T-cell derivation. An association with celiac disease is seen only rarely, and this form of intestinal lymphoma is relatively common in Asia. Both EATL Types I and II share some genetic aberrations, including chromosomal gains on 9q33–34 as well as activating mutations involving the JAK/STAT pathway.

Other PTCL can present with intestinal disease and should be distinguished from EATL. These include the EBV$^+$ extranodal T/NK-cell lymphomas, PTCL, NOS, and a rare indolent form of T-cell LPD of the GI tract recognized in the new WHO classification.[35]

Hepatosplenic T-Cell Lymphoma

Hepatosplenic T-cell lymphoma (HSTCL) presents with marked hepatosplenomegaly in the absence of lymphadenopathy. The great majority of cases are of gamma-delta T-cell origin. Most patients are male, with a peak incidence in young adults. Although patients may respond initially to chemotherapy, relapse has been seen in the vast majority of cases, and the median survival is less than 3 years. Rare long-term survival has been seen following allogeneic hematopoietic cell transplantation.

The cells of HSTCL are usually moderate in size, with a rim of pale cytoplasm. The nuclear chromatin is loosely condensed, with small inconspicuous nucleoli. The pattern of infiltration mimics the homing pattern of gamma-delta T cells with marked sinusoidal infiltration in the liver and spleen. Abnormal cells are usually present in the sinusoids of the bone marrow but may be difficult to identify without immunohistochemical stains (see Fig. 78.14B). The neoplastic cells also have a phenotype that resembles that of normal resting gamma-delta T cells. They are often negative for both CD4 and CD8, although CD8 may be expressed in some cases. CD56 is typically positive. The neoplastic cells express markers associated with cytotoxic T cells, such as TIA-1. However, perforin and granzyme B are usually negative, suggesting that these cells are not activated. Isochromosome 7q is a consistent cytogenetic abnormality and is often seen in association with trisomy 8. In addition, activating mutations involving *STAT5B*, *SETD2*, and less frequently *STAT3* have been described.[36]

Extranodal Natural Killer/T-Cell Lymphoma, Nasal Type

Extranodal NK/T-cell lymphoma, nasal type, is a distinct clinicopathologic entity highly associated with EBV. It is much more common in Asians than in Europeans.[34] Clusters of the disease also have been reported in Central and South America in individuals of Native American heritage, suggesting that ethnic background i.e., genetic risk factors, may play a role in the pathogenesis of these lymphomas. It affects adults (median age 50), and the most common clinical presentation is a destructive nasal or midline facial lesion. Palatal destruction, orbital swelling, and edema may be prominent. NK/T-cell lymphomas have been reported in other extranodal sites, including skin, soft tissue, testis, upper respiratory tract, and GI tract. The clinical course is usually aggressive, with a slightly improved median survival in patients with localized disease, in which local radiation therapy may be useful.[37] A hemophagocytic syndrome is a common clinical complication and adversely affects survival.

Extranodal NK/T-cell lymphoma, nasal type, is characterized by a broad cytologic spectrum. Although the cells express some T-cell-associated antigens, most commonly CD2, other T-cell markers, such as surface CD3, are usually absent. The cells express cytoplasmic CD3 but lack T-cell receptor gene rearrangement. In support of an NK-cell origin, the cells are usually CD56$^+$ but do not express CD57 or CD16. EBV is positive in 100% of cases by in situ hybridization (see Fig. 78.14C).

Aggressive NK-cell leukemia is a closely related entity. It presents at a younger age than extranodal NK/T-cell lymphoma, is associated with systemic disease, and a fulminant clinical course. It has a similar phenotype, EBV association, and epidemiology.

There are other EBV$^+$ T-cell and NK-cell proliferations, which are seen mainly in children. These include *systemic EBV$^+$ T-cell lymphoma, hydroa vacciniforme-like lymphoma, and severe mosquito bite allergy*, the latter usually being derived from NK-cells. All are seen most often in Asian children but are also reported in Central and South America in individuals of Native American origin. The latter two conditions affect mainly the skin and have a more indolent clinical course, whereas the systemic disease has a very aggressive clinical

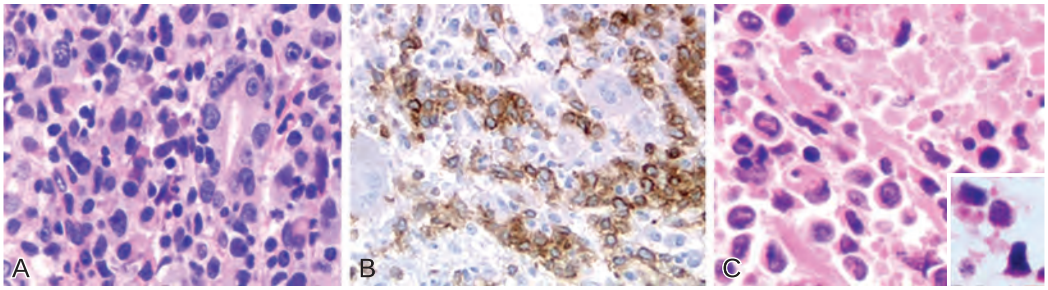

Figure 78.14 OTHER T-CELL AND NATURAL KILLER-CELL LYMPHOMAS. In enteropathy-associated T-cell lymphoma (A), there is an abnormal T-lymphoid proliferation with infiltration into the gastrointestinal glandular elements *(center right)*. Hepatosplenic gamma delta T-cell lymphoma in the bone marrow is illustrated with a CD2 stain showing the characteristic sinusoidal distribution (B). Extranodal natural killer cell/T-cell lymphoma typically has marked necrosis (C). The malignant cells are Epstein-Barr virus (EBV)–positive by in situ hybridization for EBV encoded RNA *(insert)*. *RNA*, Ribonucleic acid.

course with survival measured in weeks. Systemic EBV$^+$ T-cell lymphoma may arise in a background of chronic active EBV-infection.[3]

Hodgkin Lymphoma

Hodgkin and non-Hodgkin lymphoma have long been regarded as distinct disease entities based on their differences in pathology, phenotype, clinical features, and response to therapy. It is now accepted that the malignant cell of Hodgkin lymphoma (HL) is an altered B cell. Therefore, it is not surprising that both biologic and clinical overlaps should occur between these two lymphoma groups, as also shown by GEP in PMBL and cell lines derived from CHL. Although we have become aware of this closer relationship from the histogenetic point of view (hence the name HL), these disorders are still treated with different modalities. The preferred term of HL over Hodgkin disease reflects current knowledge concerning the nature of the neoplastic cell as a lymphocyte.

Sufficient evidence has emerged in recent years to warrant the recognition of nodular lymphocyte-predominant HL (NLPHL) as a distinct entity (discussed in the following section). Although it resembles other types of HL in having a minority of putative neoplastic cells on a background of benign inflammatory cells, it differs morphologically, immunophenotypically, and clinically from CHL. The diagnosis of CHL depends on the identification of Hodgkin and Reed-Sternberg (HRS) cells in an appropriate inflammatory background composed of small T lymphocytes, plasma cells, histiocytes, and granulocytes (often eosinophils). All cases of CHL share certain immunophenotypic and genotypic features. Neoplastic cells are CD30$^+$, CD15$^{+/-}$, CD45$^-$, and EMA$^-$. Expression of B-cell-associated antigens is seen in up to 75% of cases. However, when present, CD20 and PAX5 staining is weaker than that seen in normal B cells with variable intensity among individual tumor cells. CD79a and other B-lineage antigens (OCT2 and/or Bob.1) are downregulated and usually negative. IG and T-cell receptor genes are usually germline using whole sections, caused by the paucity of tumor cells in the inflammatory background; however, using microdissection and polymerase chain reaction (PCR) amplification clonal rearrangement of the Ig genes can generally be shown. In addition, the presence of somatic mutations indicates transit through the germinal center.

Nodular Lymphocyte-Predominant Hodgkin Lymphoma

NLPHL usually has a nodular growth pattern, with or without diffuse areas (Fig. 78.15). Nodularity may be more easily recognized using immunohistochemical stains with B-cell or follicular dendritic cell (FDC) specific antibodies. Concurrent progressively transformed germinal centers are often seen in partially involved lymph nodes or other lymph node sites. The atypical cells of NLPHL have vesicular, polylobated nuclei, and small nucleoli. These had been called lymphocytic and/or histiocytic (L&H) cells, or "popcorn" cells, but the term LP cell is now preferred. The background is predominantly lymphocytes with or without epithelioid histiocyte clusters. Plasma cells are infrequent, and eosinophils and neutrophils are rarely seen. Occasionally sclerosis may cause lesions to resemble nodular sclerosis.

The LP cells are CD45$^+$ expressing B-cell-associated antigens (CD19, CD20, CD22, CD79a), CDw75$^+$, EMA$^{+/-}$ CD15$^-$, CD30$^{-/+}$ and usually SIg$^-$ by routine techniques, although one study reported light-chain restriction. Neoplastic cells positive for IgD are more often found in young males. J chain has been demonstrated in many cases. Small lymphocytes in the nodules are predominantly B cells with a mantle-zone phenotype. However, numerous T cells are present, with T cells positive for CD57 and PD-1 (CD279) surrounding the LP cells. The proportion of T cells tends to increase over time in sequential biopsies. A prominent meshwork of FDC is present within the nodules. LP cells, when isolated by microdissection, have clonally rearranged Ig genes with evidence of somatic hypermutation.

NLPHL occurs at all ages, in adults more commonly than in children, and in males more than in females. It usually involves peripheral lymph nodes, with sparing of the mediastinum. It is usually localized at diagnosis but may be rarely disseminated. Survival is long, with or without treatment, for localized cases. However, when disseminated the prognosis is often poor. Patients with advanced-stage disease may benefit from treatment regimens used for aggressive B-cell lymphomas. Late relapses have been reported to be more common than in other types of HL; it may be associated with, or progress to, large B-cell lymphoma. Progression to a process resembling T-cell/histiocyte rich large B-cell lymphoma may also been seen, and recent data suggest that these diseases may be different ends of a spectrum, with a close biologic relationship,[38] and hence the new WHO 2017 recognized T-/HRLBCL-like transformation of NLPHL.[3]

Classic Hodgkin Lymphoma, Nodular Sclerosis

This variant is most common in adolescents and young adults, but can occur at any age; female cases equal or exceed those in males. The mediastinum is commonly involved; stage and bulk of disease have prognostic importance. Nodular sclerosis classic Hodgkin lymphoma (NSCHL) is often curable; however, in long-term survivors, the risk of secondary malignancies is increased, especially in those receiving both radiation and chemotherapy. NSCHL of the mediastinum is thought to be closely related to PMBL, and both types of tumors can be seen in the same patient, either as composite malignancy, or sequentially.[39]

The tumor has at least a partially nodular pattern, with fibrous bands separating the nodules in most cases (Fig. 78.16A). Diffuse areas may be present, as is necrosis. The characteristic cell is the

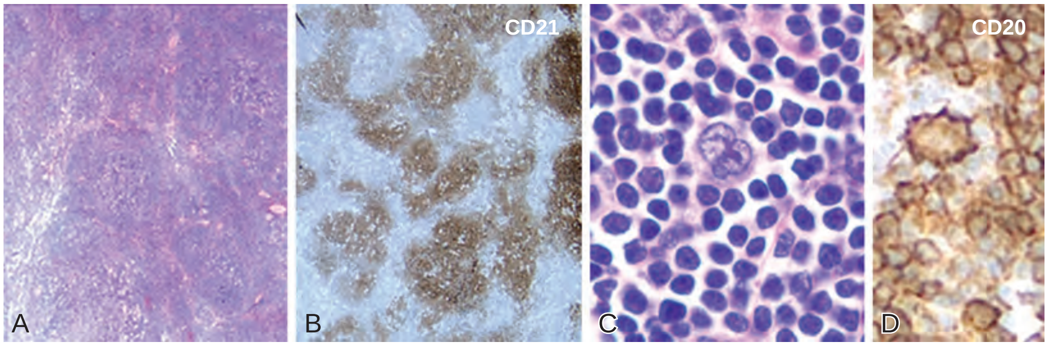

Figure 78.15 NODULAR LYMPHOCYTE PREDOMINANT HODGKIN LYMPHOMA. Low-power illustration shows vague expansile nodules that efface the lymph node architecture (A). The nodules can be accentuated with a stain for follicular dendritic cells, CD21 (B). The neoplastic cells are the so-called "LP" cells (previously called "L&H" cells or "popcorn" cells) (C). Unlike the neoplastic cells of classic Hodgkin lymphoma, these LP cells stain brightly for CD20 (D) and are typically CD45$^+$, CD30$^-$, and CD15$^-$. The current international consensus classification has indicated designation of NLPHL as nodular predominant B-cell lymphoma (NLPBL) to avoid confusion with classic Hodgkin lymphoma.

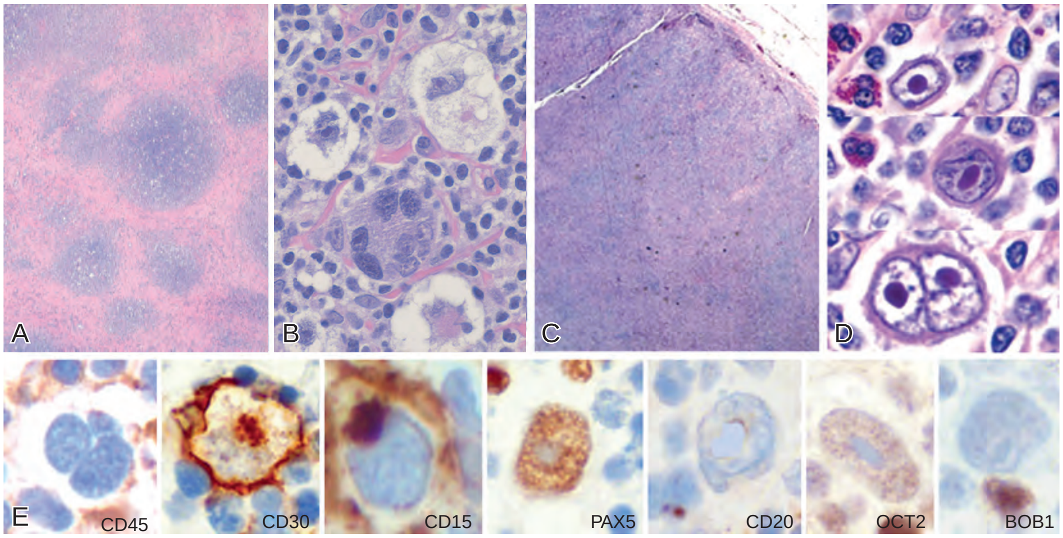

Figure 78.16 CLASSIC HODGKIN LYMPHOMA, NODULAR SCLEROSIS, AND MIXED CELLULARITY SUBTYPES. In nodular sclerosis Hodgkin lymphoma, broad bands of sclerosis typically divide the lymph node into cellular nodules (A). The nodules contain a mixed cellular infiltrate and scattered neoplastic cells with lobular nuclei and retracted cytoplasm (B). In mixed cellularity Hodgkin lymphoma, the lymph node is usually diffusely effaced with only fine fibrosis (C). Classic mononuclear, binuclear, and multinuclear Hodgkin and Reed-Sternberg cells are present (D). Hodgkin and Reed-Sternberg cells including lacunar forms are typically $CD45^-$, $CD30^+$, $CD15^+$, weakly $PAX5^+$, and $CD20^-$. The B-cell transcription factors OCT2 and BOB1 are variable but often negative (E).

lacunar-type RS cell, which may be very numerous. Diagnostic RS cells are usually also present. The background contains lymphocytes, histiocytes, plasma cells, eosinophils, and neutrophils. It can be graded according to the proportion of the tumor cells and the presence of necrosis: Grades I and II. However, grading is considered optional. The immunophenotype and genotype are characteristic of CHL. However, EBV is infrequently positive in less than 15% of cases.

Classic Hodgkin Lymphoma, Mixed Cellularity

Patients are usually adults; males outnumber females and the stage is often advanced. The course is moderately aggressive but is often curable. CHL, mixed cellularity (CHLMC) has a bimodal age distribution, with a peak in young children, and again in older adults. It is often EBV^+, seen in up to 75% of cases. Both CHLMC and the lymphocyte depleted form can be associated with underlying HIV infection. The infiltrate is diffuse, without band-forming sclerosis, although fine interstitial fibrosis may be present (see Fig. 78.16C). HRS cells are of the classic type.

Classic Hodgkin Lymphoma, Lymphocyte Depletion

This is the least common variant of CHL and is most common in older people, in HIV^+ individuals, and in non-industrialized countries. It frequently presents with abdominal lymphadenopathy, spleen, liver, and bone marrow involvement, without peripheral adenopathy. The stage is usually advanced at diagnosis. It shares many features with CHLMC and appears to represent a continuum with this variant and associated with more frequent neoplastic cells and fewer normal T cells. The infiltrate is diffuse and often appears hypocellular, owing to the presence of diffuse fibrosis and necrosis. Relative to the number of normal lymphocytes, there are large numbers of HRS cells and occasional bizarre “sarcomatous” variants, with a paucity of other inflammatory cells. The immunophenotype is characteristic of CHL. Since the histologic differential diagnosis often includes B or T-large-cell lymphoma or ALCL, IHC should be performed in most cases. EBV is positive in the majority of cases similar to the mixed cellularity subtype.

Classic Hodgkin Lymphoma, Lymphocyte-Rich

This type of CHL may be nodular or diffuse and contains relatively infrequent HRS cells, which are of the classic type, rather than the LP variants seen in NLPHL. There are infrequent eosinophils or plasma cells. In the nodular form, the HRS cells are seen at the periphery of B cell–rich nodules, mainly in the marginal zone. The neoplastic cells have the immunophenotype of classic HRS cells but morphologically may be difficult to distinguish from LP cells in some cases. Thus, in the past, many cases were misdiagnosed as NLPHL. The genetic features are similar to those of the other variants of CHL. Patients usually present with localized disease and tend to be older than patients with NLPHL.

ACKNOWLEDGMENT

The authors thank Manisha Goel, MBBS, MD, visiting hematopathologist, for proofing the final version and help with organizing the final images included in this chapter.

CHAPTER 79

ORIGIN OF HODGKIN LYMPHOMA AND THERAPEUTIC TARGETS

Ralf Küppers

More than 150 years ago, Thomas Hodgkin described several cases of a lymphoproliferative disease, later named Hodgkin disease. For a long time this malignancy, now called *Hodgkin lymphoma* (HL), has been one of the most enigmatic forms of lymphomas. This is due to several key features of the disease: First, the pathognomonic and suspected tumor cells of HL, the mononuclear Hodgkin and the bi- or multinucleated large Reed-Sternberg cells, are very rare in the tumor tissue, often accounting for only about 1% of the cells. Thus, the molecular analysis of these cells was hampered until methods became available to isolate these cells by microdissection from tissue sections. Second, the Hodgkin and Reed-Sternberg (HRS) cells have a very unusual immunophenotype that does not resemble any normal cell in the hematopoietic system. Therefore, immunophenotyping, which was very informative in revealing the cellular derivation of most other lymphoid malignancies, did not uncover the cellular origin of HRS cells. Third, only a few cell lines could be established from patients with HL, these lines were rather heterogeneous, and for hardly any of these lines, their derivation from the HRS cells in the patient was unequivocally shown. Hence, it was initially difficult to draw firm conclusions from the study of such lines. Although HL still harbors many secrets, exciting novel insights into the cellular origin of the HRS cells and the pathogenetic processes in their generation have been obtained in recent years, which will be discussed in this chapter.

CHARACTERISTICS AND ORIGIN OF HODGKIN LYMPHOMA

Classification of Hodgkin Lymphoma

HL is subdivided into classic HL, which accounts for about 95% of cases, and nodular lymphocyte-predominant HL (NLPHL). The tumor cells are called *HRS cells* in classic HL and *lymphocyte predominant (LP) cells* in NLPHL (originally the tumor cells in NLPHL were called *lymphocytic and histiocytic [L&H] cells*). Classic HL and NLPHL differ in the histologic picture, the morphology and immunophenotype of the tumor cells, and multiple clinical features. Classic HL is further subdivided into four subforms: nodular sclerosis, mixed cellularity, lymphocyte-rich classic, and lymphocyte depletion HL. Again, differences in the histologic picture and HRS cell morphology are the basis for this subtyping (see Chapter 78, for a detailed description).

B-Cell Development and Differentiation

Because we now know that HRS and LP cells are derived from B cells (see later), a brief outline of B-cell development and differentiation is given first. B cells are generated in the bone marrow from hematopoietic stem cells in a multistep developmental process. The key determinant for B-cell development is the generation of a functional B-cell receptor (BCR) that is composed of two identical immunoglobulin (Ig) heavy chains and two identical light chains, the latter of which can be of the κ or λ type. B-cell development is initiated when common lymphoid progenitors undergo gene rearrangements at the Ig gene heavy chain locus. The variable part of the antibody heavy chain is composed of three gene segments: variable (V), diversity (D), and joining (J). First, a randomly selected D_H gene segment is rearranged to one J_H gene segment. In the next step, a V_H gene segment is rearranged to a D_H-J_H joint. A heavy chain can be expressed and the developmental stage of a pre-B cell is reached if the rearrangement is in-frame and productive. In the next step, V_κ to J_κ rearrangements occur to generate a κ light chain. If this is not successful, V gene rearrangement processes take place at the λ light chain locus. B cells expressing a functional (and nonautoreactive) BCR are released into the periphery and express their BCR as IgM and IgD receptors—that is, two different classes of the heavy chain constant region. The first D_H-J_H rearrangements are not completely specific for B-lineage cells, but $V_HD_HJ_H$ rearrangements and light chain gene rearrangements are highly specific for B cells. Thus, their detection in a cell unequivocally defines that cell as a B cell. Moreover, because of the availability of multiple V, D, and J gene segments and additional diversity generated at the joining sites of the rearranging gene segments, a V(D)J rearrangement (in particular for the heavy chain locus) is unique for each B cell and thus can be used as a clonal marker for B cells deriving from the same mature B cell.

If B cells are activated through the binding of antigen to their BCR and cognate help from T-helper cells, the cells undergo a T-dependent immune response in specific histologic structures, the germinal centers (GC), in lymph nodes or other secondary lymphoid organs. In these follicles, activated B cells undergo massive clonal expansion and further diversify their BCR through two processes: somatic hypermutation and class switching. The process of somatic hypermutation introduces point mutations and some deletions and duplications at a very high rate into the Ig heavy and light chain V region genes. This randomly modifies amino acids in the V regions, and in a selection process involving follicular dendritic cells and follicular T-helper cells, B cells expressing mutated BCR with increased affinity to the stimulating antigen are positively selected, whereas B cells acquiring unfavorable mutations undergo apoptosis within the GC microenvironment (Fig. 79.1). Unfavorable mutations include destructive mutations, such as nonsense mutations, that prevent the expression of a BCR as such. Other disadvantageous replacement mutations still allow BCR expression but reduce affinity to the antigen. After multiple rounds of proliferation, mutation, and selection, positively selected B cells expressing a high-affinity BCR differentiate into long-lived memory B cells or plasma cells and exit the GC. Many GC B cells also undergo class switching before they are selected into the memory or plasma cell pool. In class switching, the originally expressed Cμ and Cδ heavy chain constant region genes (encoding IgM and IgD, respectively) are replaced by downstream located Cγ, Cα, or Cε genes, encoding IgG, IgA, and IgE heavy chains, respectively, so that antibodies with altered effector functions are generated. At all stages of their development, B lineage cells are selected for expression of the appropriate BCR, and cells failing this selection are eliminated.

Cellular Origin of Lymphocyte Predominant Cells in Nodular Lymphocyte Predominant Hodgkin Lymphoma

LP cells in NLPHL express multiple typical B cell markers, such as the surface molecules CD20 and CD79 and the transcription factors PAX5, OCT-2, and BOB1 (Table 79.1).[1] LP cells mostly lack expression of markers of other hematopoietic cell lineages, thus their immunophenotype suggests a B-cell origin. Moreover, LP cells are located in follicular structures in close association with follicular dendritic

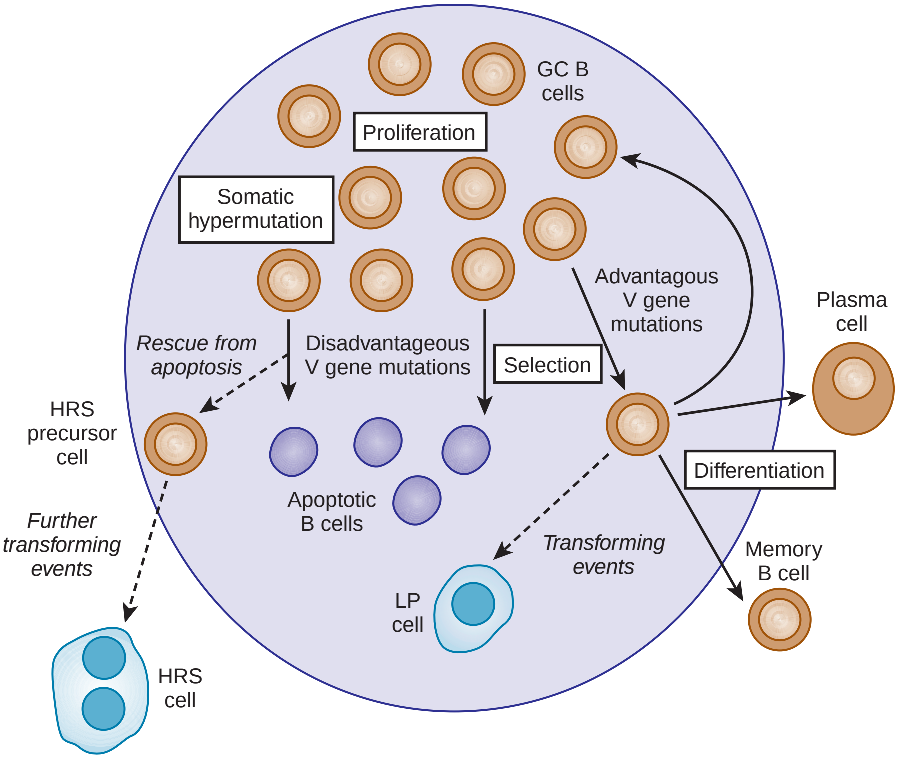

Figure 79.1 THE GERMINAL CENTER REACTION AND A SCENARIO FOR HODGKIN AND REED-STERNBERG AND LYMPHOCYTE PREDOMINANT CELL DERIVATION. Antigen-activated B cells that receive costimulatory signals from T-helper cells establish germinal center (GC) reactions in T-dependent humoral immune responses. In the GC, the activated B cells undergo massive clonal expansion in the dark zone. The proliferating GC B cells are called *centroblasts*. In the centroblasts, the process of somatic hypermutation is activated, which introduces somatic mutations at a very high rate into rearranged Ig V genes. Centroblasts migrate into the light zone and become resting centrocytes. Centrocytes are then selected based on their B-cell receptor (BCR). Most Ig V gene mutations will be disadvantageous (e.g., when they cause premature stop codons or lead to amino acid changes that reduce the affinity of the BCR to the immunizing antigen) and will cause apoptotic death of the respective B cells. GC B cells acquiring affinity-increasing mutations will be positively selected by interaction with T-helper cells and follicular dendritic cells (not shown). Positively selected centrocytes may either return to the dark zone for further rounds of proliferation, mutation, and selection, or they differentiate into memory B cells or plasma cells and exit the GC. Lymphocyte predominant (LP) cells of nodular lymphocyte predominant Hodgkin lymphoma (NLPHL) express functional Ig V genes and proliferate in a follicular microenvironment resembling GC. Thus, these cells are likely derived from selected GC B cells. Hodgkin and Reed-Sternberg (HRS) cells in classic HL often carry destructive Ig V gene mutations, indicating that they derive from GC B cells that normally would have undergone apoptosis (i.e., pre-apoptotic GC B cells). Initial transforming events in HRS cell pathogenesis might have occurred already at a pre–GC B cell differentiation stage, or they might happen in the GC. In Epstein-Barr virus (EBV)-positive cases, EBV is a good candidate for a factor that allows GC B cells with destructive Ig V gene mutations to escape from apoptosis.

cells and GC-type T-helper cells, suggesting a close relationship with GC B cells. Indeed, LP cells express the transcription factor BCL6, the main regulator of the GC B-cell differentiation program. They also express activation-induced cytidine deaminase (AID), an enzyme that regulates somatic hypermutation and class switching in GC B cells. Thus, all of these phenotypic features point to a GC B cell origin of LP cells (see Table 79.1), and this was further corroborated at the genetic level when clonally rearranged and productive Ig V region genes were amplified from isolated LP cells. These rearrangements were always somatically mutated. In some cases, an indication for ongoing somatic hypermutation was observed. Therefore, the Ig V gene analysis further strongly supported a GC B cell origin of LP cells (see Fig. 79.1). The detection of the same V gene rearrangements in all LP cells of a given NLPHL case also firmly established for the first time the monoclonality of the LP cells, a hallmark for tumor cells. A gene expression profiling study of LP cells indicated a relationship of these cells to late GC B cells on the way to becoming post-GC memory B cells.[2]

Cellular Origin of Hodgkin and Reed-Sternberg Cells in Classic Hodgkin Lymphoma

As mentioned earlier, HRS cells show a peculiar immunophenotype that does not resemble any normal hematopoietic cell type. HRS cells express markers of different cell lineages in a fraction or even most cases, including B-cell genes (e.g., PAX5, IRF4), T-cell genes (e.g., CD3, GATA3), natural killer cell genes (ID2), myeloid genes (e.g., CD15, CSF1R), and dendritic cell markers (e.g., CCL17, fascin, restin) (see Table 79.1).[1,3,4] Therefore, immunohistochemical studies could not resolve the cellular origin of HRS cells. In addition, the first cell lines established from patients with HL and presumed to be derived from HRS cells were either of B-cell origin, T-cell, or nonlymphoid origin (discussed in further detail later). The origin of HRS cells was finally clarified when HRS cells microdissected from tissue sections were analyzed for rearranged Ig V region genes. These studies revealed that HRS cells in nearly all cases carry clonal Ig heavy and light chain gene rearrangements.[1,5] Because such rearrangements are highly specific for B cells, this established their B-cell nature. Moreover, with rare exceptions, the rearranged V region genes were highly mutated, pointing to a derivation from GC or post-GC B cells.[1,5] Intraclonal V gene diversity was not observed, showing that the process of somatic hypermutation is no longer active in these cells. There is also an indication that many HRS cell clones underwent class-switch recombination, a further antigen-driven and B cell-specific process. Thus, these genetic features unequivocally demonstrate that HRS cells are derived from mature B cells that had been activated by antigen.

Surprisingly, in about a quarter of the cases of classic HL, the Ig V gene rearrangements carried clearly destructive mutations that

TABLE 79.1 Comparison of Phenotypic and Genetic Features of Hodgkin and Reed-Sternberg Cells of Classic Hodgkin Lymphoma and Lymphocyte Predominant Cells of Nodular Lymphocyte Predominant Hodgkin Lymphoma

Feature	Hodgkin and Reed-Sternberg Cells	Lymphocyte Predominant Cells
Somatically mutated Ig V genes	Yes (very rare exceptions)	Yes
Crippling Ig V gene mutations	Yes (>25% of cases)	No
Ongoing somatic hypermutation	No	Yes (moderately)
Presumed cellular origin	Pre-apoptotic GC B cells	Positively selected, mutating GC B cells
Rare cases with a T-cell origin	Yes (<5%)	No
B-cell receptor expression	No	Yes
Expression of B-cell transcription factors (e.g., OCT2, BOB.1, PU.1, PAX5, E2A)	Rarely and/or at low levels	Yes
Expression of B-cell surface antigens (e.g., CD19, CD20)	No or rarely	Yes
Expression of GC B-cell markers (e.g., BCL6, AID, HGAL, GCET)	No or rarely	Yes
Expression of molecules involved in antigen presentation and interaction with T-helper cells (e.g., CD40, CD80, CD86, MHC class II)	Yes	Yes
Expression of markers of non-B cells (e.g., CCL17, NOTCH1, GATA3, ID2, CSFR1)	Yes	No
EBV infection of tumor cells	Yes (30%–40%)	No

AID, Activation-induced cytidine deaminase; *EBV*, Epstein-Barr virus; *GC*, germinal center.

rendered originally functional V region genes nonfunctional.[1,5] Such "crippling" mutations included deletions and insertions causing loss of the correct reading frame, as well as nonsense mutations. As discussed earlier, destructive mutations regularly happen in mutating GC B cells, but this normally results very efficiently in their removal by apoptosis. Thus, it is highly likely that the GC B cells that acquired the destructive mutations already carried some transforming events, allowing them to escape apoptosis (see Fig. 79.1). Of note, most disadvantageous mutations that cause apoptosis of normal GC B cells are likely replacement mutations that reduce affinity to the antigen or interfere with the proper folding and/or pairing of the Ig heavy and light chains. These mutations cannot be easily recognized by looking at the V gene sequences. Thus, the crippling mutations likely represent only the "tip of the iceberg," and we have speculated that HRS cells, as a rule, derive from the pool of pre-apoptotic GC B cells (see Fig. 79.1).[1,5]

Decisive steps in HL pathogenesis, therefore, become effective or take place in GC B cells. Thus, although some final transforming events may well occur when HRS precursor cells have already left the GC microenvironment, for the reasons discussed earlier, classic HL is considered as a GC B cell–derived malignancy. A global gene expression study comparing HRS cells to various mature B cell subsets revealed that the gene expression pattern of HRS cells is most similar to that of the rare normal CD30$^+$ B cells, so that HRS cell development may be closely linked to these normal B cells.[6]

T Cell–Derived Classic Hodgkin Lymphoma

The observation that in a fraction of cases the HRS cells express several T-cell markers (e.g., CD3, granzyme B, perforin, T cell intracellular antigen 1) prompted studies aimed to clarify whether in such cases the HRS cells derive from T cells. Analysis of HRS cells from several cases with T-cell marker expression showed that most of these cases nevertheless are B cell–derived. However, several cases were identified that lacked Ig V gene rearrangements and that showed clonal T-cell receptor gene rearrangements.[7,8] Thus, these cases have a T-cell origin. Because the cellular origin of a lymphoma clone is a key factor for current lymphoma classification, it is a matter of debate whether lymphomas with HRS cells of T-cell origin should be called *HL* or whether they should be considered a rare, separate type of T-cell lymphoma. Notably, in gene expression studies of HL cell lines, HDLM-2 (a T cell–derived HL cell line) clustered more closely to B cell–derived HL cell lines than to other T-cell lymphoma lines, suggesting that B cell– and T cell–derived HRS cells have a similar gene expression pattern.

Hodgkin Lymphoma Cell Lines

Tumor cell lines are valuable tools for detailed genetic, biochemical, and functional studies of a malignancy. Thus, there have been many attempts to establish such lines from patients with HL. However, this has proved to be very difficult, and less than 10 HL cell lines exist. The main reason for the difficulty in growing HRS or LP cells in culture is most likely their dependence on survival signals from the cellular microenvironment in the disease-affected lymph nodes. Of note, all of the existing HL lines are derived from patients at end stage and were not established from lymph nodes, but rather from peripheral blood, bone marrow, or pleural effusions. This suggests that only when the HRS cells have become independent from the lymph node microenvironment in the patient do they also have a chance to survive in suspension culture. The existing and available HL lines are L428, L540, L591, L1236, KM-H2, HDLM-2, UHO-1, SUP-HD1, and DEV (Table 79.2). Most lines are of B-cell origin, but HDLM2 and L540 are T cell–derived. L591 is the only HL line that is EBV-positive. Among primary cases of classic HL, approximately 30% to 40% show EBV infection of the HRS cells (see further details later). Notably, L591 cells do not have the typical EBV gene expression pattern of primary EBV-infected HRS cells, which should be kept in mind when using this line for gene expression or functional studies. The DEV line was originally reported as being derived from a case of classic HL, but subsequent more detailed phenotypic and gene expression studies indicated that this is indeed the only existing cell line from a patient with NLPHL. Although the phenotype and genotype of these lines fit well with their presumed origin from HRS cells (or LP cells in the case of DEV), L1236 is the only cell line for which the derivation from the HRS cell clone of the patient it was established from was unequivocally proven. Originally, the CO line was also published as an HL cell line. However, later studies showed that this line represents a cell culture contamination. Also, the HD-Myz line was for a long time considered to be a classic HL cell line. However, it was later discovered that the phenotype of the line differs in key aspects from the phenotype of the primary HRS cells of the respective patient. Even more important, HD-Myz lacks Ig- and T-cell receptor gene rearrangements and is presumably of myeloid origin. The nonlymphoid origin of HD-Myz argues against its derivation from HRS cells; thus, this line should not be used as a model for HL.

Although the HL cell lines are a valuable (and practically the only) tool for functional studies with HRS cells, it needs to be taken into consideration that the cells are adapted to growth in suspension culture in the absence of their normal microenvironment. Indeed, a comparison of the gene expression pattern of primary HRS cells and

TABLE 79.2 **Characteristics of Hodgkin Lymphoma Cell Lines**[a]

Cell Line	Hodgkin Lymphoma Subtype	Cellular Origin	Oncogenes or Tumor Suppressor Genes with Genetic Lesions	Remarks
L428	Classic	B cell	*B2M*, *NFKBIA*, *NFKBIE*, *PTPN1*, *SOCS1*, *TP53*	
L540	Classic	T cell	*PTPN1*	
L591	Classic	B cell		Only EBV-positive line

[a] A few additional lines have been published (HO, ZO, HD-70, HKB-1), but these have not been used in published studies in recent years, so it is unclear to the author whether they still exist, and very little is known about their phenotypic, functional, and genetic features.
EBV, Epstein-Barr virus; *HRS*, Hodgkin and Reed-Sternberg.

classic HL cell lines revealed more than one thousand differentially expressed genes, including many genes regulating the extracellular matrix, proliferation, and chemokine production and signaling.[9]

Relationship Between Hodgkin Cells and Reed-Sternberg Cells

The population of HRS cells is always composed of a mixture of mononuclear Hodgkin cells and bi- or multinucleated Reed-Sternberg cells. It is thus an intriguing question how these two types of cells are related to each other. It was proposed that the fusion of two independent cells might be involved in the generation of Reed-Sternberg cells from Hodgkin cells. It was also discussed whether the whole HRS cell clone could derive from a cell fusion (e.g., a fusion of a B cell with a non-B cell). Such a scenario was attractive because it might have provided an explanation for the mixed immunophenotype and the usually aneuploid karyotype of the HRS cells. However, generation of the HRS cell clone through the fusion of two separate cells was excluded by molecular studies.[10] Indeed, there is now firm evidence from studies of HL cell lines that Reed-Sternberg cells develop from mononuclear Hodgkin cells through a process of incomplete cytokinesis.[11] When Hodgkin cells attempt to undergo cell division, the final separation of the daughter cells often fails, and these cells undergo refusion, giving rise to a binucleated Reed-Sternberg cell.[11] Reed-Sternberg cells have little further proliferative potential, so that the mononuclear Hodgkin cells are the principal proliferative compartment of the HRS cell clone.

Potential Hodgkin and Reed-Sternberg Precursor or Stem Cells

Another interesting question is whether the rare CD30$^+$ HRS cells represent the whole tumor cell clone in the HL tissue or whether further tumor clone members are present among the smaller, CD30$^-$ cells in the microenvironment. In a single-cell Ig V gene analysis of EBV-positive HRS cells and EBV-infected CD30-negative cells, it was found that the HRS cells and the small CD30$^-$ EBV-infected B cells carried distinct V gene rearrangements in nearly all instances.[12] Because EBV infection of HRS cells is a clonal event, in that in EBV$^+$ HL cases all members of the tumor clone should carry the virus, this finding was taken as an argument that the HRS cell clone does not have additional members among CD30-negative lymphocytes.

In several types of tumors, cancer stem cells were identified. These cells are defined as rare cells that have a particular proliferative potential and that sustain the tumor clone, whereas the bulk of the tumor clone lacks the potential to regrow into a full tumor. One study described the existence of HRS precursor cells in HL that fulfill at least some key features of cancer stem cells. However, this finding was criticized because the markers for a clonal relationship between the HRS and non-HRS cells were unreliable and even argued, in part, against a relationship of the cells.[13] Thus there is currently no convincing evidence for the existence of CD20$^+$BCR$^+$ HRS stem cells. In any case, it needs to be considered that HRS cells carry clonal and somatically mutated Ig V gene rearrangements; thus, if HRS stem cells exist, they must be mature GC-derived B cells that carry the same Ig gene rearrangements and mutation pattern as the HRS cells.

The issue of potential subpopulations among the HRS cell clone with specific features in terms of proliferative potential and chemotherapy resistance was also addressed by searching for *side population cells*, which are defined as cells that extrude the Hoechst dye 33342, usually because they express drug transporters of the ABC family, such as the multidrug resistance 1 gene. In several types of tumors, side population cells were shown to share features with cancer stem cells (e.g., increased proliferative potential and chemotherapy resistance). Side population cells were indeed detected at low frequency (about 0.5% of cells) in some HL cell lines, and these cells showed increased resistance to chemotherapeutic drugs.[14,15] The side population cells had the phenotype of small Hodgkin cells and they were positive for CD30 and negative for CD19 and CD20. Hence, these cells are different from the cells identified earlier as potential HRS stem cells. Notably, side population cells were able to reestablish the full HRS cell clone upon subcloning. However, not all HL cell lines showed side population cells,[14,15] arguing against a general role of these cells in the maintenance of the HRS cell clone. Moreover, although side population cells were also identified in cell suspensions of HL lymph nodes, it remains to be clarified whether these cells belong to the HRS cell clone.

Lessons From Composite Lymphomas

Composite lymphomas are very rare lymphomas in which two distinct lymphomas, often an HL and a non-Hodgkin lymphoma (NHL), occur in the same patient. In a strict definition of composite lymphoma, this happens concurrently, but there are also cases where an HL may occur either before or after an NHL in the same patient. There are a few cases where the two lymphomas are not related to each other and hence represent the chance occurrence of two unrelated malignancies developing in parallel in a patient. However, in most composite and sequential HL and NHL that have been molecularly studied for their clonal relationship, it was found that the lymphomas share a common origin, even in instances where sequential lymphomas occurred several years apart from each other.[16] The detailed study of the rearranged Ig V genes of such cases revealed that, although, in many cases, the clonally related V region genes of the lymphomas share a number of somatic mutations, there are often additional mutations that were present only in the HRS cells and others only in the NHL B cells.[16] This showed that the two lymphomas have a common precursor, most likely a mutating GC B cell, and that the two lymphomas most likely developed from two distinct members of the GC B cell clone (Fig. 79.2). Thus, these composite lymphomas usually do not represent the transformation of one lymphoma into the other but, rather, the parallel development of the two malignant clones from a common, premalignant precursor cell. It is likely that some transforming events were already present in the common precursor, but distinct daughter cells of this GC B cell later acquired different mutations, leading to the generation of the two distinct B-cell malignancies (see Fig. 79.2). Therefore, composite lymphomas are intriguing models to study the multistep transformation process in lymphomagenesis. In initial studies of several composite lymphomas for shared and distinct transforming events, examples for such genetic lesions were indeed identified.

A further important aspect of the molecular studies of composite lymphomas is that they provide further evidence for the derivation of HRS cells in classic HL from GC B cells because the clonal relationship with shared and distinct somatic Ig V gene mutations of an HRS cell clone and a typical GC B cell-derived lymphoma (e.g., follicular lymphoma or diffuse large B-cell lymphoma) strongly supports a common GC B-cell origin of both malignancies.

The Role of Epstein-Barr Virus in Classic Hodgkin Lymphoma

In about 40% of cases of classic HL in the Western world, and about 90% of childhood HL cases in Central and Southern America, HRS cells are infected by EBV. Molecular analyses of EBV$^+$ cases showed that EBV infection of HRS cells is a clonal event (i.e., EBV infected or was already present in the founder cell of the HRS cell clone). EBV-positive HRS cells typically show a latency II gene expression pattern characterized by expression of the EBV nuclear antigen 1 (EBNA1) and the two latent membrane proteins 1 and 2a (LMP1 and LMP2a, respectively). EBNA1 is essential for the replication of the EBV episome in proliferating cells. LMP1 is an oncogene, and one of its main functions is to cause constitutive nuclear factor kappa B (NFκB) activation by mimicking an activated CD40 receptor. LMP2a has a cytoplasmic motif that resembles the signaling motif of the BCR. LMP2a can, on the one hand, diminish BCR signaling by recruiting BCR signaling components away from the BCR, but on the other hand, it mimics a tonic BCR signal. Strikingly, all HRS cell clones with clearly destructive Ig V gene mutations that prevent the expression of a BCR were found to be EBV-positive.[17] Hence, it appears that in GC B cell precursors of HRS cells that acquired BCR-destructive mutations, EBV is essential to rescuing these cells from apoptosis upon loss of BCR expression. This scenario is supported by studies showing that EBV can rescue BCR-deficient GC B cells from apoptosis and that LMP2a has an important role in this process.[18] Whether the BCR-mimicking function is still important in the established HRS cell clone is unclear. The downregulation of most components of BCR signaling in HRS cells indicates that LMP2a does not have this role in the established HRS cell clone.

Genetic Lesions in Hodgkin and Reed-Sternberg and Lymphocyte Predominant Cells

The molecular analysis of HRS and LP cells for genetic lesions is hampered by the rarity of these cells. Nevertheless, we are now aware of a number of transforming events, especially for HRS cells. The recognition of the constitutive activity of the NF-κB transcription factor, which is normally only transiently activated in lymphocytes, prompted studies of whether genetic mutations cause this deregulated activity. Inactivating mutations in the gene *NFKBIA*, which

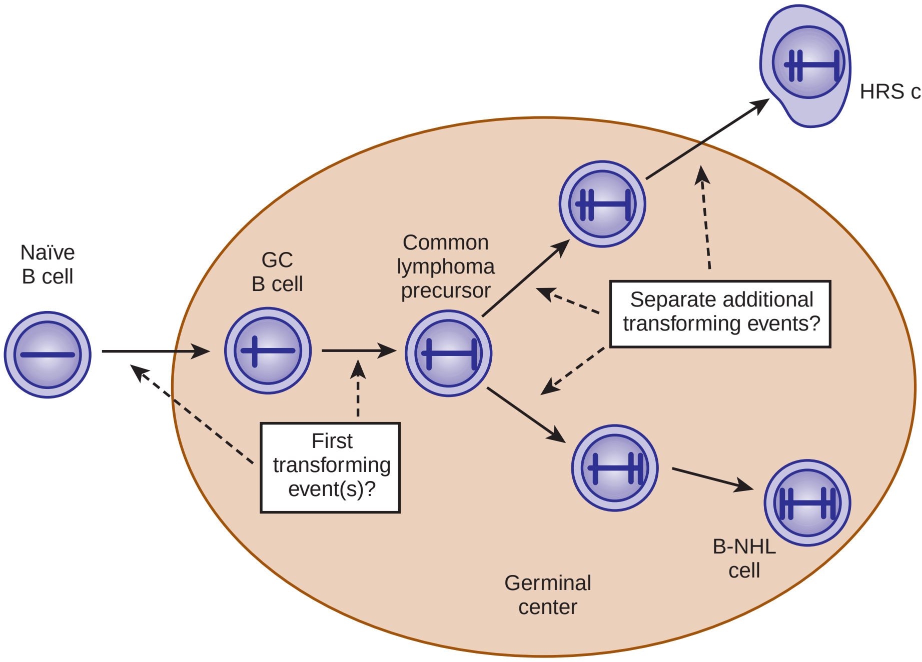

Figure 79.2 SCENARIO FOR THE GENERATION OF COMPOSITE LYMPHOMAS. Composite lymphomas are very rare combinations of two distinct lymphomas, often a classic Hodgkin lymphoma (HL) and a non-Hodgkin lymphoma (NHL). Detailed molecular analysis of rearranged Ig V genes in several combined HL and B-cell derived NHL revealed that, in most instances, the two lymphomas are clonally related. Notably, the pattern of both shared and distinct V gene mutations in the majority of these cases revealed that the two lymphomas share a common precursor, but developed separately from this precursor. The direct clonal relationship of Hodgkin and Reed-Sternberg (HRS) cells with typical germinal center (GC) B cell-derived NHL is a further strong argument for a GC derivation of HRS cells. The horizontal line within the cells indicates an Ig V region gene; the vertical lines indicate somatic Ig V gene mutations. (*Modified from Bräuninger A, Hansmann ML, Strickler JG, et al. Identification of common germinal center B-cell precursors in two patients with both Hodgkin's disease and non-Hodgkin's lymphoma. N Engl J Med. 1999; 340:1239.*)

encodes the main inhibitor of NFκB (i.e., IκBα) were detected in 10% to 20% of cases of classic HL (Fig. 79.3).[1] Also, mutations in the *NFKBIE* gene were found. Genomic gains of the *REL* gene, encoding one of the NFκB factors, are present in about 40% of classic HL. Inactivating mutations in *TNFAIP3*, encoding a further negative regulator of NFκB, were detected in 40% of HRS cell clones.[19] Interestingly, most cases with *TNFAIP3* mutations were EBV-negative,[19] suggesting that EBV infection and *TNFAIP3* mutations are alternative mechanisms in HL pathogenesis, thereby, further supporting a pathogenetic role of EBV in HL development. Reestablishing wild-type TNFAIP3 in HL cell lines reduced NFκB activity and survival, establishing that TNFAIP3 functions as a tumor suppressor gene in this lymphoma.[19] Rare mutations were also found in *TRAF3*, encoding a negative regulator of the noncanonical NFκB pathway. Finally, the NIK kinase gene (*MAP3K4*), encoding a major activating factor for the noncanonical NFκB pathway, shows gains in 20% of classic HL.

Although LP cells of NLPHL also show constitutive NFκB activity,[2] no destructive mutations were found in *TNFAIP3* and *NFKBIA* in these cells, and LP cells are not infected by EBV. In some NLPHL *REL* gains were found. Thus, the mechanisms causing NFκB activation in HRS and LP cells are largely different.

A second signaling pathway that shows constitutive activity in HRS cells and mutations in various pathway members is the JAK/STAT (Janus kinase/signal transducer and activator of transcription)pathway, the main pathway for cytokine signaling. Upon activation of cytokine receptors, JAK kinases bind to the receptors and become activated. The activated JAKs then phosphorylate and thereby activate STAT (Janus kinase/signal transducer and activator of transcription) factors, which upon phosphorylation and dimerization translocate into the nucleus and function as transcription factors. Frequent genomic gains of *JAK2* and also rare translocations involving this gene have been detected in HRS cells. SOCS1, a main inhibitor of this signaling pathway, is inactivated by somatic mutations in the HRS cells in about 40% of cases of classic HL. Destructive mutations in the *PTPN1* gene were detected in HRS cells in 20% of cases.[20] PTPN1 is a phosphatase that, among other functions, negatively regulates STAT activity. An exome sequencing study of HRS cells revealed activating *STAT6* mutations in about 30% of cHL cases.[21]

Notably, the genomic region on 9p24, which harbors the *JAK2* gene and shows gains in HRS cells, also encompasses the gene *JMJD2C* that encodes a histone demethylase, and the programmed death 1 (PD-1) ligand genes *PD-L1* and *PD-L2*.[22,23] PD-1 ligands inhibit PD-1–expressing T cells and may contribute to the immunosuppressive microenvironment in HL.[22] A functional role of JMJD2C in HRS cells is indicated from the finding that the downregulation of its expression in HL cell lines is toxic for these cells.[23] Thus, a single

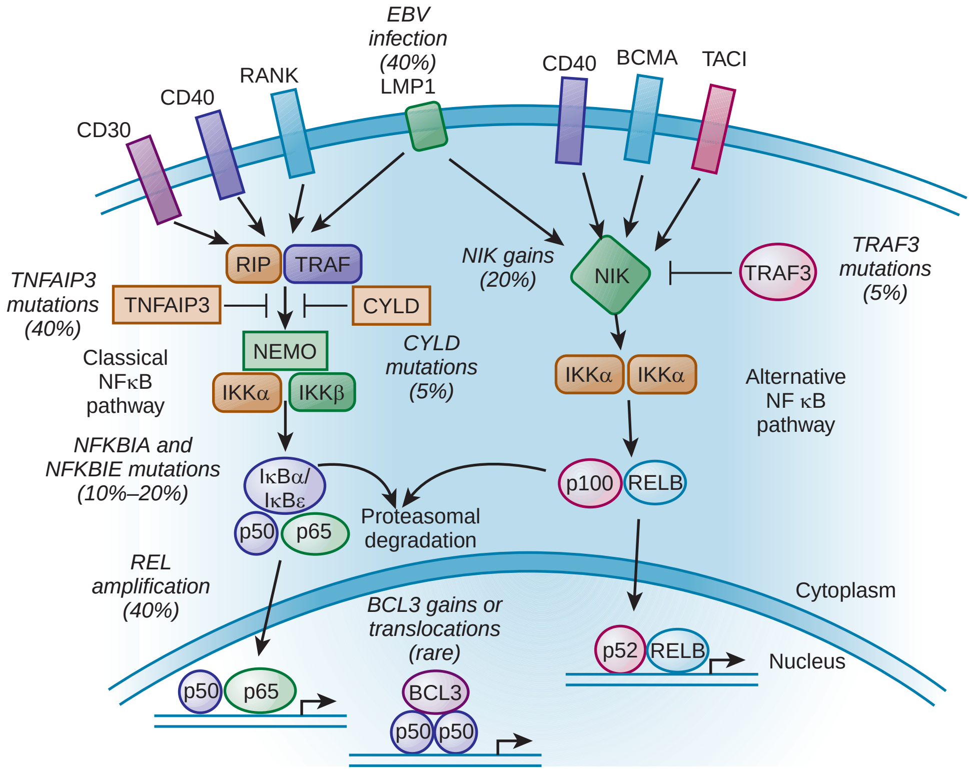

Figure 79.3 MECHANISM OF NFκB ACTIVATION IN HODGKIN AND REED-STERNBERG CELLS. A classic and an alternative NFκB signaling pathway are distinguished. In the classic NFκB pathway stimulation of numerous receptors (e.g., RANK, CD30, and CD40) leads via TNF receptor–associated factors (TRAFs) and other associated factors, such as the receptor-interacting protein (RIP), to activation of the IKK complex. The IKK complex is composed of IKKα, IKKβ, and NEMO. The activated IKK complex phosphorylates the NFκB inhibitors IκBα and IκBε which are encoded by the *NFKBIA* and *NFKBIE* genes, respectively. The phosphorylation marks the IκB factors for ubiquitinylation and subsequent proteasomal degradation. Thus, the NFκB transcription factors (e.g., p50/p65 or p50/REL heterodimers) are no longer retained in the cytoplasm and translocate into the nucleus where they activate multiple genes. The signal transduction from TRAFs/RIP to the IKK complex can be inhibited by A20/TNFAIP3, which removes activating ubiquitins from RIP and TRAFs and additionally links ubiquitins to these molecules to mark them for proteasomal degradation. In the alternative NFκB pathway, activation of receptors such as BCMA, CD40, and TACI causes stimulation of the kinase NIK (encoded by the *MAP3K4* gene), which then activates an IKKα complex. Activated IKKα processes p100 precursors to p52 molecules that translocate as active p52/RELB NFκB heterodimers into the nucleus. HRS cells show the constitutive activity of the classic and alternative NFκB signaling pathways. This activity is mediated by diverse mechanisms, including receptor signaling through CD40, RANK, BCMA, and TACI; genomic *REL* and *MAP3K4* amplifications; destructive mutations in the *TNFAIP3*, *NFKBIA*, and *NFKBIE* genes; and signaling through the EBV-encoded latent membrane protein 1. HRS cells may also harbor nuclear BCL3/$(p50)_2$ complexes, and in a few cases, the strong BCL3 expression appears to be mediated by genomic gains or chromosomal translocations of this gene. In rare instances, inactivating mutations in the inhibitory factors TRAF3 and CYLD have been found. (*Modified and updated from Küppers R. The biology of Hodgkin's lymphoma. Nat Rev Cancer. 2009; 9:15.*)

genetic lesion, the genomic gain on 9p24, can affect four genes with pathogenetic roles in HRS cells.

Because disturbed apoptosis seems to be a key aspect of classic HL pathogenesis, numerous regulators of apoptosis were also studied in HL cell lines and/or primary HRS cells. Mutations in the *TP53* gene were found in three HL cell lines and a few primary cases.[24] Mutations in the *CD95* gene were found in less than 10% of cases, and no mutations were found in the genes of the CD95 signaling components CASP8, CASP10, and FADD.[24] Moreover, no mutations were detected in the proapoptotic gene *BAD*; mutations in *ATM* are also very rare.[24]

Chromosomal translocations, usually involving one of the Ig loci and an oncogene, are a hallmark of most B cell lymphomas. Also in classic HL, chromosomal breaks involving the Ig loci were detected by fluorescence in situ hybridization in about 20% of cases. However, the translocation partners are in most cases unknown. In a few instances, *BCL2*, *BCL3*, *BCL6*, or *MYC* were identified as partners of the translocations. This also includes composite lymphomas where the clonally related classic HL and the B-cell NHL were found to carry the identical translocation—for example, a *BCL2*-IgH translocation in a composite classic HL/follicular lymphoma.[16] Notably, Ig locus–associated translocations usually function by causing deregulated expression of the translocated oncogene that has been brought under the control of the Ig regulatory elements, which are active in normal B cells and B-cell NHL. Because the Ig loci are largely silenced in HRS cells, it is still unclear whether the partner genes of Ig locus-associated translocations in HRS cells are still active and pathogenetically relevant. Perhaps the translocations were important during the early stages of HRS cell pathogenesis, when the lymphoma precursor cells still had a B-cell gene expression program but became less important during later stages of the multistep transformation process. Alternatively, it should also be considered that translocations might function by mechanisms other than Ig enhancer–driven oncogene overexpression (e.g., promoter replacement or tumor suppressor gene inactivation).

HRS cells show a heterogeneous pattern of major histocompatibility complex (MHC) class I and II expression. Recurrent translocations involving the MHC class II transactivator gene *CIITA* were found in about 15% of classic HL.[25] These translocations involved heterogeneous partner genes and seemed to function by impairing the CIITA function and hence dampening MHC class II expression. The gene of the MHC class I component β-2-microglobulin (*B2M*) is mutated in more than half of classic HL according to a recent study.[26] Down modulation of MHC class I is often a strategy of cancer cells to evade attack by cytotoxic T cells.

Recent exome or targeted sequencing analyses of isolated HRS cells or from circulating tumor DNA in plasma uncovered a number of additional genetic lesions in HRS cells.[21,26,27] These include mutations in the exportin 1 gene (*XPO1*), which encodes a factor regulating nuclear export of various molecules, the mutation in the gene encoding the G protein GNA13, and inactivating mutations in *ITPKB*, which encodes an inhibitory factor in AKT signaling. Moreover, recurrent mutations in *CSF2RB*, encoding a common component of the receptors for interleukin-3, interleukin-5, and granulocyte-macrophage colony-stimulating factor were observed in several studies.

For LP cells of NLPHL, few genetic lesions are known. *SOCS1* mutations occur frequently in LP cells, and translocations involving the *BCL6* gene are often found in these cells.[24] BCL6 encodes a transcription factor that orchestrates the GC B-cell differentiation program and that has an oncogenic function when constitutively expressed in B cells. A study published in 2016 identified highly recurrent mutations in the genes of the serine/threonine kinase SGK1, the phosphatase DUSP2, and the AP-1 transcription factor JUNB in LP cells.[28]

THERAPEUTIC TARGETS

For a long time, poly-chemotherapy and/or radiation therapy (or in advanced stages hematopoietic stem cell transplantation) were the only options for the treatment of HL patients. However, recently, several types of targeted immune therapies have been established, with very promising results. A main breakthrough was the development of a toxin-coupled anti-CD30 antibody, brentuximab vedotin, for the treatment of classic HL. CD30 seems to be an ideal molecule for a targeted therapy, because this surface receptor is, on the one hand, universally and most strongly expressed by HRS cells of classic HL, and, on the other hand, it is expressed by only a few normal cells in the body, reducing the risk for severe side effects. CD30 is currently also used as a target for an approach with gene-modified autologous T cells, which are engineered to express a chimeric anti-CD30 antibody and T-cell receptor. A further breakthrough was the recognition of high therapeutic effectiveness of antibodies against PD-1 or PD-L1.[29] PD-1 is expressed by various types of immune cells and signaling through this receptor has suppressive effects on the immune cells. HRS cells express PD-L1 and PD-L2, as already described above, and use this for immune evasion. The antibodies against PD-1 or PD-L1 interfere with this inhibitory effect and thereby allow reactivation of the immune cells that then can attack the HRS cells. Notably, it is not yet clear which immune cells are mainly responsible for the therapeutic effect of the anti-PD1 and anti-PD-L1 antibodies. As HRS cells often lack MHC class I expression, they should not be targetable by $CD8^+$ cytotoxic T cells, so that cytotoxic $CD4^+$ T cells and natural killer cells may play a role. Clinical trials are also ongoing with another checkpoint inhibitor, namely an antibody against CTLA4, which is a further immunosuppressive factor.

CONCLUSIONS AND FUTURE DIRECTIONS

It is now firmly established that HRS and LP cells stem from mature B cells. A few cases with features of classic HL and a T-cell origin of the HRS cells exist. HRS cells in classic HL appear to derive from crippled GC B cells, whereas LP cells likely originate from antigen-selected GC B cells. HRS cells show deregulated activation of multiple signaling pathways, and numerous genetic lesions have been identified that contribute to the deregulated activation of the NFκB and JAK/STAT pathways. HRS cells show a nearly complete loss of the B-cell gene expression program.[3] As normal GC B cells are stringently selected to express a functional, high-affinity BCR, the lost B-cell phenotype may be related to the origin of HRS cells from preapoptotic GC B cells: by losing the B cell–typical gene expression program, the HRS cell precursors may escape from the pressure to undergo apoptosis as "failed B cells." It has been speculated that transient hypoxic conditions in the GC may contribute to the initial "dedifferentiation" of the HRS precursor cells because exposing human B cells to hypoxia induces several phenotypic changes in these cells toward an HRS cell phenotype.

The recent molecular biologic findings about HRS cells also offer some explanations for the typical and rather unique immunophenotypic heterogeneity of the HRS cells between cases and also among HRS cells of a given clone. The heterogeneity is likely due in part to different combinations of transforming events between HL cases. Moreover, the coexpression of multiple master regulators of different hematopoietic cell lineages (e.g., PAX5, ID2, NOTCH1) within one HRS cell clone may cause major fluctuations in gene expression between clone members by the fluctuation of the competing transcription factors. Finally, because HRS cells are intimately interacting with multiple types of cells in their microenvironment, both by cellular interactions and through cytokines and chemokines, variations in the direct surrounding of HRS cells may cause differences in gene expression in these cells.

Further work is needed to fully understand the transforming events that lead to the generation of malignant HRS and LP cell clones, but with the availability of new methods, such as massive parallel sequencing of tumor genomes, it can be expected that major progress will be made in the near future.

Finally, the recent detection of cell-free DNA presumably derived from HRS cells in the blood plasma of patients with HL[30] offers exciting novel possibilities to monitor the disease, and this tumor-specific DNA may become a useful biomarker.

CHAPTER 80

HODGKIN LYMPHOMA

Anas Younes, Ann S. LaCasce, Graham Collins, Bouthaina Dabaja, and Ahmet Dogan

Hodgkin lymphoma (HL) is an uncommon lymphoproliferative malignancy arising from B cells. It can affect all age groups but is most common in young adults. HL is the first adult malignancy to demonstrate the curative potential of combination chemotherapy. Today, more than 80% of patients with newly diagnosed HL can now expect to be cured of their disease.[1]

The challenge now, particularly since many affected patients are young, is not only to improve cure rates further, but also to minimize the risk of long-term complications of treatment, which can impact quality of life and survival. Accordingly, HL provides a very important clinical model for ongoing cancer research involving both the development of novel targeted agents and the study of late effects of cancer therapy.

Traditionally, the choice of frontline therapy for HL has been determined by clinical stage and prognostic factors. A combined modality approach with chemotherapy and radiotherapy (RT) remains the standard of care for those with early-stage disease, although the routine use of RT has been challenged recently. For those presenting with more advanced stage diseases, chemotherapy alone has been widely adopted. The availability of highly effective chemotherapy combinations and sensitive imaging tests has allowed the development of less toxic therapeutic strategies for those with limited disease. This includes using more limited radiation fields such as involved-field radiotherapy (IFRT), more recently involved-site radiotherapy (ISRT) and, in some centers, involved node radiotherapy (INRT) and a reduction in the number of chemotherapy cycles. This more focused treatment delivery has allowed efficacy to be preserved while exposure to unnecessary toxicity is reduced.

The management of HL continues to evolve ^{18}fluorodeoxyglucose (FDG). Positron emission tomography (PET) imaging has emerged as a useful tool for assessing response and to guide further therapy that may allow RT—free regimens in appropriate patients. This, coupled with ongoing research to identify better biologic prognostic factors, is likely to allow for a more accurate risk-adapted approach to management, with the future treatment of patients with HL being tailored to the needs of the individual. In addition, improved understanding of the molecular mechanisms underlying HL has hastened the development of more effective, and often less toxic, targeted therapies for use either as monotherapy or in combination with traditional chemotherapy to augment efficacy and decrease overall toxicity.

EPIDEMIOLOGY AND ETIOLOGY INCIDENCE AND AGE OF ONSET

HL is a rare B-cell malignancy accounting for less than 1% of all cancers with approximately 9200 new cases diagnosed in the United States and approximately 5500 new cases diagnosed in Europe each year.[2,3] The incidence of HL varies with economic status and geographic location. In developed countries it is associated with a bimodal age of onset distribution, with an early, larger, peak occurring in young adults aged between 20 and 40 years and a second, smaller, peak occurring in those over 55 years. In contrast, in developing countries, the disease predominantly occurs in childhood, with the incidence decreasing with age. Overall, men are affected slightly more frequently than women.

Etiology

The exact cause of HL remains unknown and clearly defined risk factors for the development of the disease are lacking. However, certain associations with its development have been identified. Although a clear genetic cause has not been established, familial susceptibility has been suggested by both an apparent increased risk among siblings of patients with HL, as well as concordance for HL observed in monozygotic twins. Increased maternal education, early birth order, low number of siblings and single-family dwellings in childhood have all also been positively associated with the occurrence of HL in younger patients.

Epstein-Barr virus (EBV)—positive Reed-Sternberg (RS) cells are found in approximately 40% of patients with HL using modern molecular techniques.[4] The incidence of EBV positive HL among those with a past history of serologically proven infectious mononucleosis appears to be higher than those without previous exposure.[5] EBV may play a role in promoting RS survival and has been associated with the increased production of molecules that are involved in mechanisms of immune escape, in turn influencing the microenvironment that supports HL development.

PATHOBIOLOGY OF HODGKIN LYMPHOMA

The World Health Organization (WHO) classifies HL into two distinct disease types: classic HL (cHL), representing 95% of all cases, and nodular lymphocyte-predominant HL (NLPHL), accounting for only 5%.[6] Both cHL and NLPHL are neoplasms composed of a minor component of atypical large neoplastic cells, usually accounting for less than 10% of all cells that are present in a reactive nonneoplastic background.[7,8] However, based on their distinct clinical and molecular genetic features, it is now evident that cHL and NLPHL are two biologically distinct entities. Within cHL, four histologic subtypes are recognized based on the morphology of the neoplastic cells, composition of the nonneoplastic infiltrate, and overall nodal architecture: nodular sclerosing (NSCHL), mixed cellularity (MCCHL), lymphocyte-depleted (LDCHL), and lymphocyte-rich (LRCHL). Of these, NSCHL predominates, accounting for 70% of cases of cHL in Europe and the United States (Table 80.1). The rate of NSCHL, however, varies with geographic location and socioeconomic status and is much lower in developing countries, where MCCHL predominates. Furthermore, NSCHL occurs less frequently in patients infected with HIV, among whom the more common presenting subtype, again, is MCCHL.

Nodular Lymphocyte-Predominant Hodgkin Lymphoma

Typical cases of NLPHL show partial or complete nodal architectural effacement by a macronodular proliferation (Fig. 80.1A), where the nodules are composed of scattered neoplastic cells termed *lymphocyte-predominant (LP) cells*, formerly known as L&H cells.[9] LP cells are large with single folded or multilobulated nucleus with distinct but smaller nucleoli than RS cells. Because of their highly complex nuclear lobation, they have also been widely referred to as “popcorn cells” (see Fig. 80.1B). The background nonneoplastic infiltrate is composed of predominantly small B cells and a variable number of histiocytes. Mixed inflammatory cells such as eosinophils and neutrophils are rare to absent.

LP cells typically express B-cell markers including CD20 (see Fig. 80.1C), PAX-5, and CD79a. In addition, LP cells consistently express CD45, and the B-cell transcriptional factors OCT-2 and BOB.1, that are usually not expressed by RS cells. In contrast to RS cells, LP cells typically lack CD15 and CD30 expressions.[10] In keeping with their germinal center B-cell origin, LP cells are consistently positive for BCL6, although CD10 is usually not expressed. They may express EMA (epithelial membrane antigen) in a subset of LP cells in approximately 50% of the cases, and variably express IRF4/MUM1. A subset of cases with expression of IgD, and unique pathological and clinical features has also been described.[11] EBV-encoded RNA (EBER) and latent membrane protein-1 (LMP1) are consistently negative.

TABLE 80.1 **Frequency of Histologic Subtypes of Hodgkin Lymphoma**

Classic Hodgkin lymphoma (cHL)	95%
• *Nodular sclerosis classic Hodgkin lymphoma (NSCHL)*	70%
• *Mixed cellularity classic Hodgkin lymphoma (MCCHL)*	20–25%
• *Lymphocyte-rich classic Hodgkin lymphoma (LRCHL)*	5%
• *Lymphocyte-depleted classic Hodgkin lymphoma (LDCHL)*	<1%
Nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL)	5%

The nodules in NLPHL are typically supported by an expanded meshwork of follicular dendritic cells that can be highlighted by CD21 and CD35, and populated by small B cells that are positive for immunoglobulin (Ig) M and IgD. There are a variable number of T cells, a significant proportion of which is positive for CD4, CD57, and programmed cell death protein 1 (PD-1) which frequently form rosettes around the LP cells (see Fig. 80.1D). Immunoarchitectural patterns as determined relative abundance and distribution of reactive B cells and T cells have been described. Limited data suggests that as the disease progresses the nodules acquire T-cell-rich features, at the end resembling T-cell histiocyte-rich large B-cell lymphoma. These histological variants are associated with increased chance of advanced disease and relapse.[12]

Genetic studies performed on microdissected LP cells show clonally rearranged Ig genes with high load of somatic mutations in the variable region, indicating the presence of ongoing mutations and consistent with germinal center B-cell derivation of NLPHL. In contrast to cHL, the Ig rearrangement is functional with detectable Ig mRNA transcripts. Acquired somatic mutations described in NLPHL include BCL6 gene rearrangements, mutations affecting PAX5, PIM1, RHOH, MYC, SGK1, DUSP2, and JUNB.[13]

Classic Hodgkin Lymphoma

cHL is characterized by the presence of RS cells and their morphologic variants in a reactive background composed of mixed inflammatory cells (except in lymphocyte-rich variant).[8] *Classic (diagnostic) RS cells* are large binucleated or multinucleated cells with pale chromatin, distinct nuclear membrane, single prominent eosinophilic,

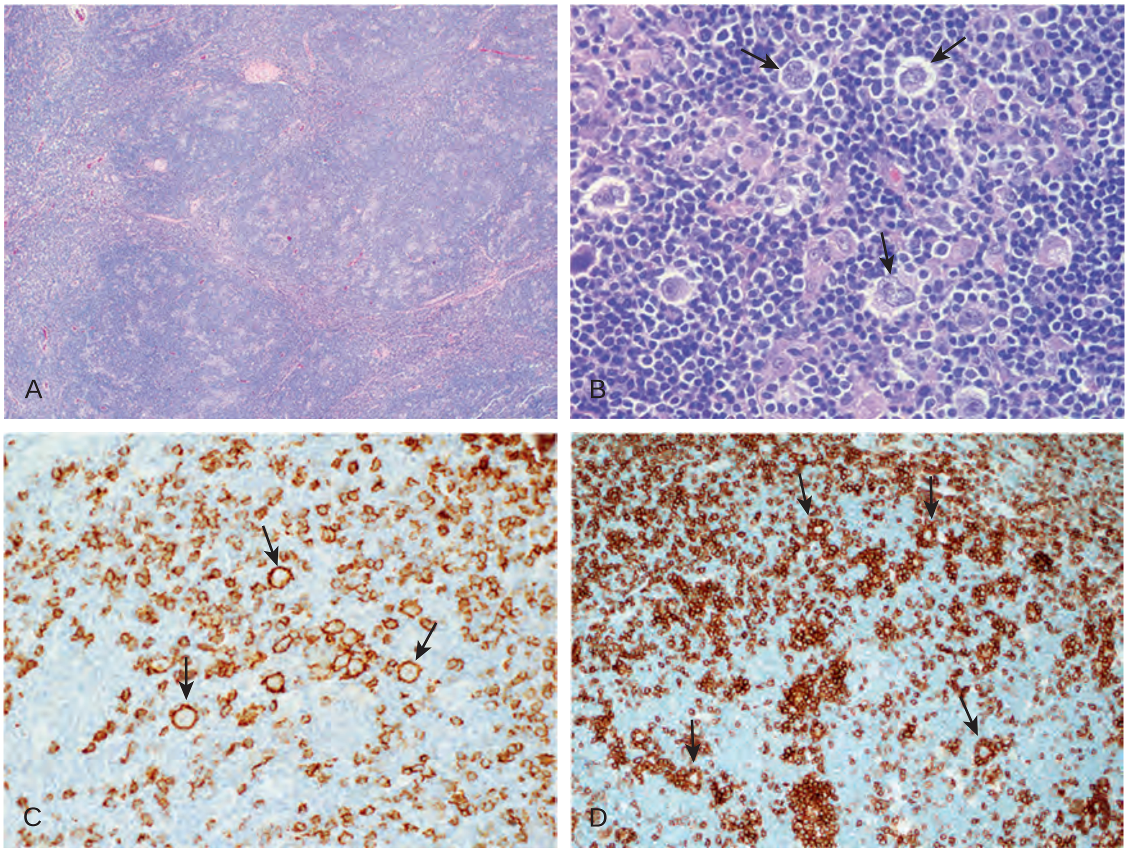

Figure 80.1 A CASE OF NODULAR LYMPHOCYTE-PREDOMINANT HODGKIN LYMPHOMA. The lymph node architecture is effaced by multiple expansile nodules with mottled appearance (A). Within the nodules there are scattered atypical large cells (lymphocyte-predominant *[LP]* cells) with single folded or multilobated nucleus with distinct but relatively small nucleoli (B). The LP cells are positive for CD20 *(arrows)* with similar strong expression intensity as background small reactive B cells (C). The background infiltrate is composed of numerous programmed cell death protein 1 *(PD-1)*—positive T cells that frequently form rosettes *(arrows)* around the LP cells (D).

inclusion-like nucleolus in each nuclear lobe, and abundant amphophilic cytoplasm (Fig. 80.2A). Mononuclear variants with otherwise similar cytonuclear features are termed *Hodgkin cells* (see Fig. 80.2B). *Mummified cells* are degenerated RS and Hodgkin cells with pyknotic nuclei and condensed cytoplasm (see Fig. 80.2C). These variants are usually seen in various proportions in all four subtypes of cHL. In addition, *lacunar cells* are characteristic of nodular sclerosis cHL but usually not other subtypes, which have abundant pale cytoplasm that frequently retracts in formalin fixed tissue, creating an empty space (lacunae) around the cells (see Fig. 80.2D).

NSCHL is characterized by sclerotic nodal capsule and presence of collagenous bands traversing through the nodal parenchyma, imparting a prominent nodular pattern (Fig. 80.3A). Within the nodules there are a variable number of RS cells and variants, especially lacunar cells, with a background of mixed inflammatory cells composed of a variable proportion of small lymphocytes, histiocytes, plasma cells, eosinophils, and neutrophils. The RS cells and variants may be singly dispersed or form confluent aggregates/sheets.

In *MCCHL* the lymph node architecture is usually diffusely obliterated, although an interfollicular pattern may be seen in early involvement. In contrast to NSCHL, the nodal capsule is not thickened and there are no collagenous bands of fibrosis (see Fig. 80.3B). RS cells and variants are usually easily identified and dispersed throughout the nodal tissue in a mixed inflammatory background. In comparison to NSCHL, MCCHL is more often associated with higher stage disease and EBV positivity and is more likely seen in the HIV-infected patient population.

LRCHL is a relatively recently defined subtype of cHL characterized by the presence of RS cells in a background of almost exclusively small lymphocytes, with a paucity or absence of eosinophils and neutrophils. The vast majority of the cases exhibit nodular growth pattern, although a rare diffuse variant has also been described. In the vast majority of the cases the affected lymph node is obliterated by multiple expansile nodules with expanded mantle zones and regressed, eccentrically located residual germinal centers (see Fig. 80.3C).

LDCHL is exceedingly rare (<1% of cHL) with a highly variable histologic appearance, but in all cases characterized by a relative predominance of RS cells in comparison to the background lymphocytes. Some cases are characterized by scattered RS cells in a diffusely fibrotic background containing histiocytes, fibroblasts, and few lymphocytes. In others, sheets of bizarre, pleomorphic, or anaplastic-appearing RS cells are present, imparting a sarcomatous appearance (see Fig. 80.3D).

The immunophenotypic profile of RS cells in all cHL subtypes is similar. RS cells are strongly positive for CD30 with membranous and Golgi pattern in nearly all cases (Fig. 80.4A), and CD15 with variable staining intensity in approximately 80% of the cases (see Fig. 80.4B). Consistent with their B-cell derivation, RS cells express PAX-5 in almost all cases (95%) but with weaker intensity when compared with the surrounding nonneoplastic small B cells (see Fig. 80.4C). However, in keeping with their defective B-cell program, RS cells lack Ig production as evidenced by absence of J chain, and are negative for most other B cell–associated antigens: CD20 (expressed in only 20% to 30% of cases; often only in a subset of RS cells with weak/variable intensity), CD19, and CD79a; as well as B-cell transcriptional factors octamer transcription factor-2 (OCT-2) and B-cell oct-binding protein 1 (BOB.1) (each expressed in 10% of cases; coexpression is rare). RS cells are almost always positive for IRF4/MUM1 and negative for CD45 and EMA, features that may

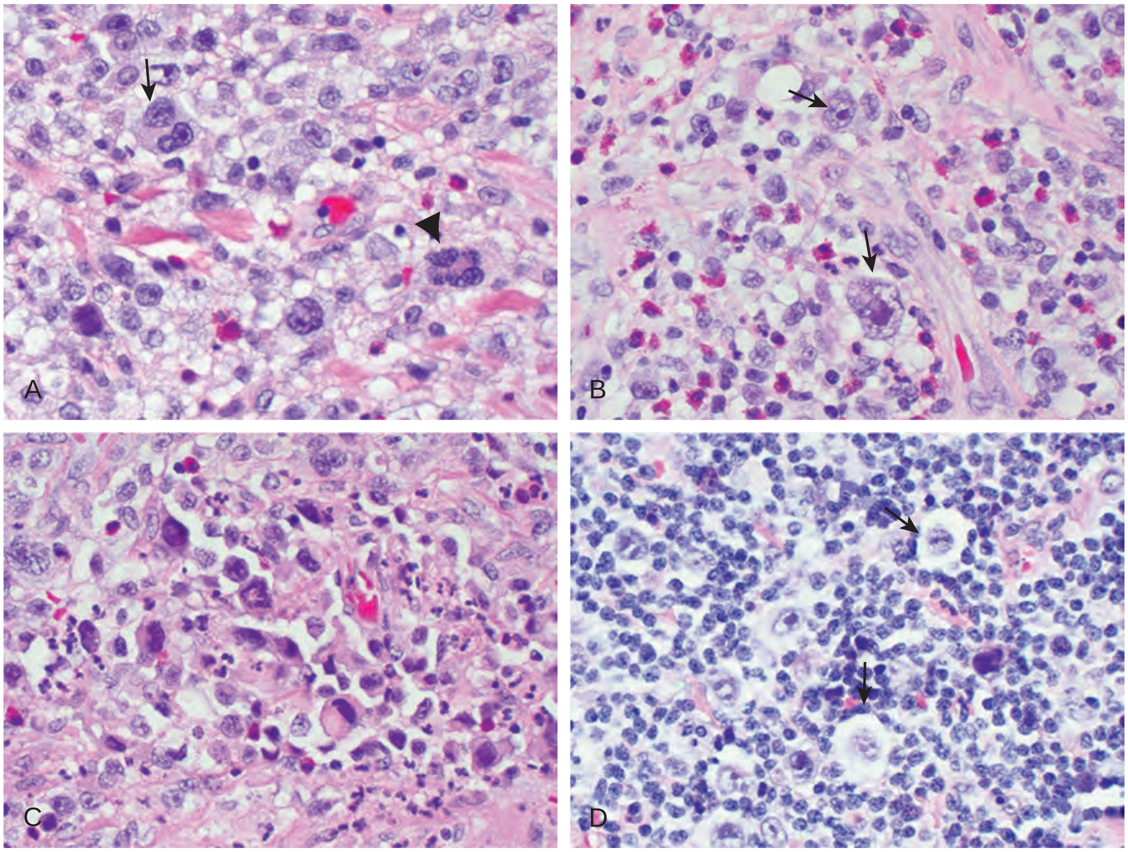

Figure 80.2 MORPHOLOGIC VARIATIONS OF REED-STERNBERG CELLS IN CLASSIC HODGKIN LYMPHOMA. The diagnostic Reed-Sternberg *(RS)* cells (A) are large binucleated *(arrow)* or multinucleated cells *(arrowhead)* with distinct nuclear membrane, prominent nucleolus in each nuclear lobe, and abundant amphophilic cytoplasm. Hodgkin cells are mononuclear variants of RS cells with similar cytonuclear features (B); numerous eosinophils and granulocytes are noted in the background. Mummified cells are degenerated RS and Hodgkin cells with pyknotic nuclei and condensed cytoplasm (C). Lacunar cells, characteristic of nodular sclerosis classic Hodgkin lymphoma (cHL), have abundant pale cytoplasm which frequently retracts in formalin fixed tissue (D).

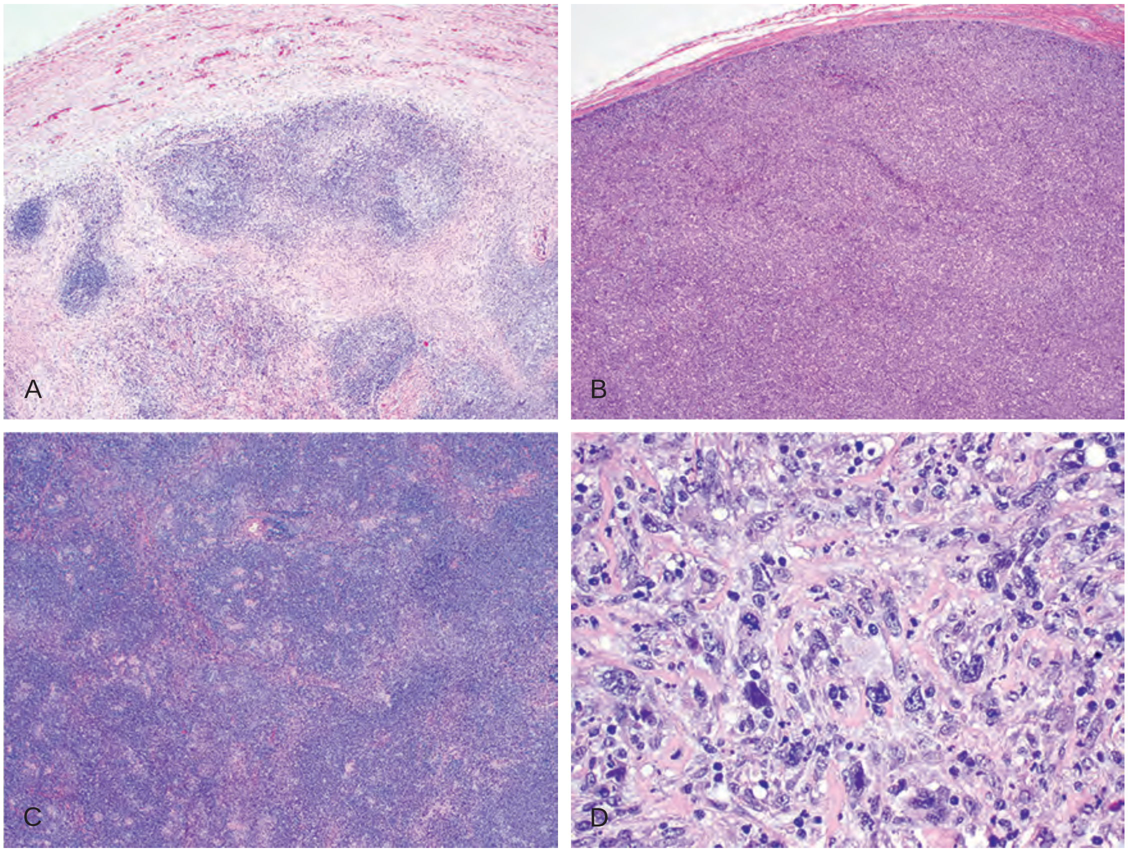

Figure 80.3 HISTOLOGIC PATTERNS OF CLASSIC HODGKIN LYMPHOMA SUBTYPES. Nodular sclerosis classic Hodgkin lymphoma (cHL) characteristically shows multinodular pattern on low magnification, where the nodules are surrounded by broad collagenous bands. The nodal capsule is markedly sclerotic (A). In mixed cellularity cHL, the lymph node architecture is diffusely obliterated by the neoplastic infiltrate. The nodal capsule is not sclerotic and there are no collagenous bands of fibrosis (B). A case of lymphocyte-rich cHL where the affected lymph node is obliterated by multiple expansile nodules, with strikingly similar morphologic appearance to nodular lymphocyte-predominant Hodgkin lymphoma (C). A case of lymphocyte-depleted cHL with presence of numerous pleomorphic/anaplastic appearing Reed-Sternberg (RS) cells (D).

help distinguish cHL from NLPHL. Expression of other hematopoietic lineage—associated markers, such as T cells (CD4, granzyme B), dendritic cells (fascin, CCL17), and myeloid cells (colony stimulating factor 1 receptor and α_1-antitrypsin) is also often present. EBV LMP1 and/or EBER expression (see Fig. 80.4D) by RS cells is seen in approximately 40% of cHL cases overall in Western countries, but mostly in MCCHL and LDCHL and less frequently in NSCHL and LRCHL. However, an association with EBV is seen in up to 90% of cHL cases in developing countries and nearly all cases in the HIV patient population.

The nonneoplastic background lymphocytes, with the exception of LRCHL, are composed of predominantly T cells with marked predominance of CD4-positive cells that coexpress CD25 and FOXP3, consistent with immunosuppressive regulatory T cells (TReg). In addition, there is a significant population of TH2 cells. TReg and TH2 cells are attracted by cytokines (CCL5, CCL17, and CCL22) secreted by RS cells. In HIV-infected patients there is often a predominance of CD8-positive T cells. In contrast to NLPHL, CD57-positive T cells are not increased in number in cHL.

Polymerase chain reaction studies performed on RS cells procured by microdissection demonstrated that in the vast majority of cHL cases (>98%), the RS cells harbor clonal IgH gene rearrangement. The rearranged IgH shows a high load of somatic hypermutation in the variable region without evidence of ongoing mutation, consistent with germinal center or postgerminal center B-cell derivation. Rare cases harboring T-cell receptor gene rearrangements have also been documented. Genetic structural alterations that modulate tumor cell biology and the tumor microenvironment have been recently reported. These include mutations leading to loss of MHC class I and class II expressions,[14,15] upregulation of PDL-1 expression by gene amplification or rearrangements,[16] deregulation of nuclear factor-kappa B (NF-κB) pathway,[17,18] and activation of janus kinase (JAK)/signal transducer and activator of transcription (STAT) pathway (Fig. 80.5).[19]

DIAGNOSIS AND STAGING

Diagnosis

The definitive diagnosis of HL must be made pathologically via excision biopsy of an affected lymph node or other suspected organ. Core needle biopsy is deemed inferior to excision biopsy because of the unique architecture of the lymph node in HL that comprises a relatively dilute population of malignant cells. The presence of RS cells in cHL, and LP cells in NLPHL in tissue biopsy, provides the basis for discriminating between these two major diagnostic subtypes, with immunophenotypic profiling representing a crucial adjunct for all new cases of HL.

Staging

Stage of disease is the major determinant of prognosis for patients with newly diagnosed HL, and accurate assessment is paramount when deciding upon optimal therapy.[20] The current staging system used for patients with HL is the Lugano classification, which was based on the Cotswold-modified Ann Arbor classification system (Table 80.2). Recently, a simplified staging and response assessment criteria were proposed.[21] An integrated PET/computed tomography

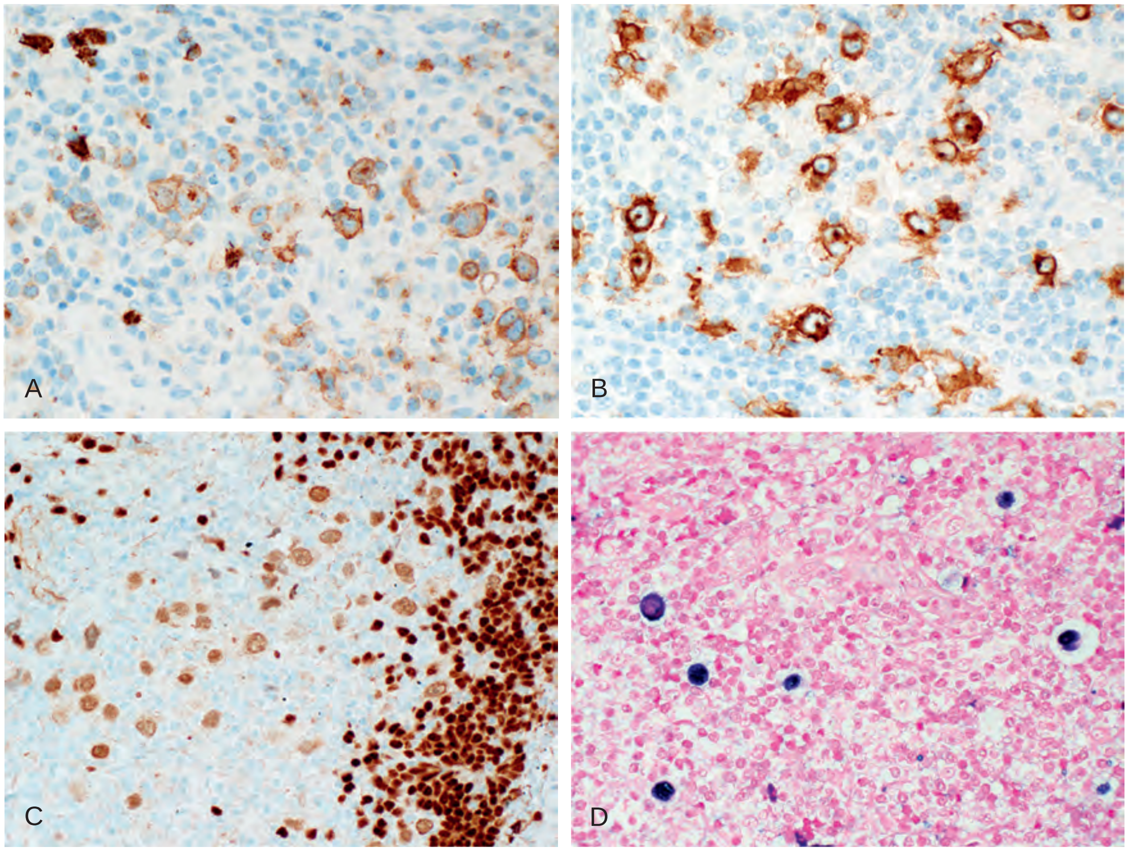

Figure 80.4 IMMUNOPHENOTYPIC PROFILE OF REED-STERNBERG (RS) CELLS IN CLASSIC HODGKIN LYMPHOMA. The RS cells and variants are positive for CD15 (A) and CD30 (B), with characteristic membranous staining and Golgi accentuation. These cells are positive for PAX-5, but with weaker intensity in comparison to background small reactive B cells (C). The RS cells are positive for Epstein-Barr virus (EBV) as demonstrated by in situ hybridization for EBV-encoded RNA/EBV-encoded RNA (EBER) (D).

(CT) is used for staging of ^{18}F-2-deoxyglucose (FDG)—avid lymphomas, and reinforced its recommendation as an effective response assessment tool both early on during treatment and at the end of treatment to establish remission status.[22]

Bone marrow involvement occurs in less than 5% of patients with HL at diagnosis. Until recently, following pathologic diagnosis with excisional node biopsy, a bone marrow biopsy was also required as part of routine staging for all patients with newly diagnosed HL. However, because of the high sensitivity of PET/CT for bone marrow involvement, bone marrow biopsy is no longer mandated for the routine staging of patients with newly diagnosed HL, unless PET/CT imaging is unavailable.[22]

In addition to excisional node biopsy and staging with PET/CT, assessment of the peripheral blood represents an important part of the diagnostic workup for patients with newly diagnosed HL with particular respect to risk stratification and treatment choice. Complete blood count, erythrocyte sedimentation rate (ESR), and serum biochemistry including C-reactive protein, alkaline phosphatase, lactate dehydrogenase, liver function tests, renal function tests, and albumin are required as part of standard care, and screening for HIV and hepatitis is strongly advised. In addition, given the potentially damaging effects of chemotherapy and RT, certain pretreatment investigations including cardiac and pulmonary function tests, thyroid function tests, reproductive counseling, and serum pregnancy testing, may also be warranted in selected patients.

CLINICAL FEATURES

The importance of an accurate clinical history in facilitating the management of patients with HL should not be underestimated. Certain symptoms may provide clues as to the likely stage of disease or lead to further investigations that might identify additional sites of disease. This may result in important treatment modifications. An accurate past medical history, particularly with regards to lung, heart, and kidney function, is also crucial in highlighting those organs that might benefit from further investigation before commencing therapy, to ensure that treatment choices are both effective and safe for the individual.

Systemic symptoms that are known to influence prognosis in patients with HL include night sweats, fever, and weight loss. These constitutional symptoms have come to be known as “B symptoms” and their importance in HL is reflected by their inclusion as key components of the Cotswold-modified Ann Arbor staging system. B symptoms are a presenting feature in approximately 30% of patients with advanced stage HL. A particular type of fever that is considered characteristic of HL historically, is the Pel-Ebstein fever, which typically follows a swinging pattern, occurring on a daily basis for many weeks, with intermittent afebrile periods occurring between episodes. Other well-described clinical features associated with HL include fatigue, chronic pruritus, which may be an early sign of disease in up to 15% of patients, and the presence of a pain localized to the site of involved lymphadenopathy that is precipitated by the consumption of alcohol.

PROGNOSTIC FACTORS, RISK STRATIFICATION, AND TREATMENT GROUPS

Prognostic factors have helped to predict the likely outcome for individual patients with HL at diagnosis. Clinical stage, presence of systemic symptoms, and tumor burden continue to be important prognostic factors in HL, and, in addition to disease histology and

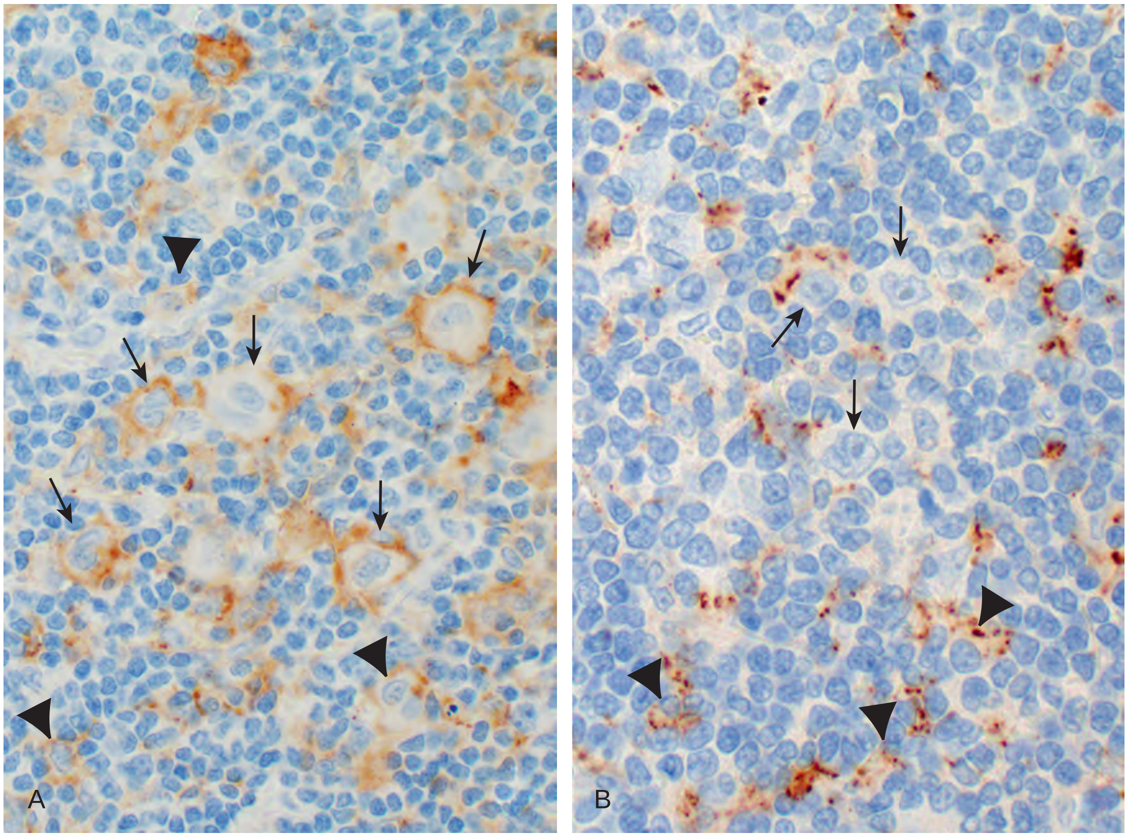

Figure 80.5 IMMUNOHISTOCHEMICAL ANALYSIS OF BETA-2-MICROGLOBULIN AND PDL-1 EXPRESSION IN CLASSIC HODGKIN LYMPHOMA. (A) A case of nodular sclerosis classic Hodgkin lymphoma (cHL) showing loss of beta-2-microglobulin in Reed_Stenberg cells, and (B) upregulation of PDL-1 secondary to rearrangement of *PDL-1/PDL-2* gene locus as demonstrated by fluorescence in situ hybridization (FISH) analysis *(inset)*. Blue probe represents centromeric region of chromosome 9 whereas green and red probes flank the *PDL-1/PDL-2* gene locus. The rearrangement affecting one of the three copies of the *PDL-1/PDL-2* locus lead to separation of green and red signals.

TABLE 80.2 Cotswold-Modified Ann Arbor Staging System for Hodgkin Lymphoma

Stage	Criteria
I	Disease affecting a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer ring)
II	Disease affecting two or more discrete lymph node regions confined to the same side of the diaphragm
II	Disease affecting two or more discrete lymph node regions or lymphoid structures on both sides of the diaphragm
IV	Disease that has spread to one or more extranodal site (that does not meet the criteria for E) or extralymphatic structure including involvement of the bone marrow, liver, or lungs
Designation	**Criteria**
A	Absence of B symptoms[a]
B	Presence of B symptoms[a]
S	Involvement of the spleen
E	Single extranodal site or involvement of an extranodal site that is contiguous to an involved nodal region.
X	Bulky disease as defined as >1/3 mediastinum at its widest part or a nodal mass >10 cm at its greatest diameter.

[a] B symptoms: constitutional symptoms including night sweats, fevers, or weight loss (>10% over 6 months).

anatomic stage, are widely used for risk stratification and subsequent selection of appropriate initial therapy.[23]

HL patients have traditionally been divided into two distinct prognostic groups according to clinical stage at diagnosis: early-stage disease, accounting for 45% of newly diagnosed patients, and advanced-stage disease, accounting for 55% of newly diagnosed patients.

The category of early-stage HL includes patients with stages I or II. Early-stage disease may also include patients with B symptoms, bulky disease, or extension to adjacent sites. Additional prognostic factors were developed to stratify early-stage disease into early "favorable" and early "unfavorable" disease subgroups. Early stage I or II HL is considered "favorable" if it is limited to an area above the diaphragm and is not associated with other risk factors. Early stage I or II HL is considered "unfavorable" in the presence of other risk factors related to age, tumor burden, ESR, and number of involved nodal areas (Table 80.3).[24] Early-unfavorable disease is often referred to as Intermediate stage disease and these terms may be used interchangeably. Thus, early-stage HL is a heterogeneous group and treatment algorithms have been developed for different subgroups based on these prognostic factors and response criteria.

The prognostic criteria for advanced-stage HL again vary among different cooperative groups. The European Organisation for Research and Treatment of Cancer (EORTC) defines advanced stage as those patients with clinical stage III–IV disease only, whereas the German Hodgkin Study Group (GHSG) also includes those patients with clinical stage IIB disease and a large mediastinal mass and/or extranodal disease involvement in their definition (see Table 80.3).

Following the identification of more specific and more widely applicable prognostic factors, the International Prognostic Score (IPS) was developed as an internationally accepted means of distinguishing those patients with newly diagnosed advanced HL who might be cured

TABLE 80.3 Prognostic Factors in Early and Advanced-Stage Hodgkin Lymphoma

Prognostic Group	EORTC	GHSG	NCCN
Early-favorable	CS I-II without risk factors (supra-diaphragmatic)	CS I-II without risk factors	CS IA-IIA without risk factors
Early-unfavorable (Intermediate)	CS I-II with ≥1 risk factor (supra-diaphragmatic)	CS I-IIA with ≥1 risk factor C/D but not A/B	CS I-II with ≥1 risk factor
Advanced	CS III-IV	CS IIB with risk factors A/B CS III/IV	CS III-IV
Prognostic factors	(A) Bulky mediastinal mass[a] (B) Age ≥50 years (C) Elevated ESR (>50 mm/h without B symptoms; >30 mm/h with B symptoms[b]) (D) ≥4 nodal areas (out of 5 supra-diaphragmatic EORTC areas)	(A) Bulky mediastinal mass[a] (B) Extranodal disease (>1 lesion) (C) Elevated ESR (>50 mm/h without B symptoms; >30 mm/h with B symptoms[b]) (D) ≥3 nodal areas (out of 11 GHSG areas)	(A) Bulky mediastinal mass[a] (B) Bulk >10 cm (C) Elevated ESR (>50 mm/h without B symptoms) (D) B symptoms (E) ≥4 nodal areas (out of 17 Ann Arbor regions)

No. of Prognostic Factors	% of Patients	5-year FFP (%)	5-year OS (%)
0–1 (low-risk)	29	79	90
2–3 (intermediate-risk)	52	64	80
4–7 (high-risk)	19	47	59

FFP, Freedom from progression; *OS*, overall survival.

by standard treatment, and, therefore, avoid overtreatment for those whom standard treatment might fail. In 1998, based on a multivariate analysis of survival data from 5141 patients with newly diagnosed advanced HL treated between 1983 and 1992, seven adverse prognostic factors were identified as being statistically meaningful when predicting 5-year freedom from progression (FFP) and overall survival (OS): age ≥45 years, male sex, albumin less than 40 g/L, hemoglobin less than 10.5 g/dL, Ann Arbor stage IV, leukocytosis ≥15 × 10^9/L, and lymphocyte count less than 0.6 × 10^9/L.[23] Five-year FFP was 84% for those patients with no adverse prognostic factors, and each additional factor reduced FFP by 7%, with four to seven factors representing an FFP of 40%. Three risk groups were established as a result, allowing therapy to be chosen according to these specific clinical characteristics, with the consensus being that higher risk patients should receive more intensive therapy (Table 80.4).

Treatment According to Prognostic Group

For patients with early stage disease, therapeutic options include combined modality therapy and chemotherapy alone.[24] In patients receiving combined modality therapy, the number of cycles of chemotherapy and dose of radiation are determined by whether patients present with favorable or unfavorable disease. Increasingly, however, given the desire to avoid late toxicities associated with radiation, PET adapted approaches with chemotherapy alone are being recommended.[25–27] The omission of RT is associated with a slightly higher risk of relapse compared to chemotherapy, only without an impact on OS (Table 80.5).

TREATMENT OF EARLY-STAGE HODGKIN LYMPHOMA

Early-Stage Nodular Lymphocyte-Predominant Hodgkin Lymphoma

Patients with NLPHL typically present with localized peripheral lymphadenopathy in the absence of B symptoms, bulky disease, and mediastinal involvement. The clinical behavior of NLPHL is more similar to that of indolent non-Hodgkin lymphoma, as opposed to cHL.

The optimal treatment for NLPHL remains poorly defined.[28,29] Although no randomized trials exist specifically for early stage NLPHL, ISRT is typically employed.[30] A single center series of 93 patients treated with RT alone reported a 10-year progression with free survival rates of 85% and 61% for stage I and stage II patients respectively, with OS rates of 94% and 97%.[31] For patients with stage I or contiguous stage II disease, ISRT is typically preferred, though observation for surgically excised patients is preferred by some physicians and is commonly used in pediatrics. Patients with more extensive disease or B symptoms, particularly those with splenic and/or upper abdominal involvement may have occult transformation to aggressive lymphoma. In the absence of transformation, optimal front-line therapy is unclear, and patients are often managed with chemoimmunotherapy including rituximab, as is used in advanced stage disease.

Early-Stage Classic Hodgkin Lymphoma

Recent strategies for the management of early-stage cHL focus on balancing long term control of disease with late effects of therapy and include combined modality therapy as well as chemotherapy only approaches.[32] Therapeutic options are guided by prognostic risk groups.[33]

In the GHSG HD10 study, 1370 patients with low-risk disease (one or two non-bulky sites of nodal disease), were randomized to 2 versus 4 cycles of ABVD (adriamycin, bleomycin, vinblastine, and dacarbazine) followed by 20 versus 30 Gy of IFRT. Outcomes were excellent in all groups with freedom from treatment failure over 90% and OS greater than 96% at 5 years, thus establishing 2 cycles of

TABLE 80.5 Standard Treatment Approach According to Prognostic Group

Early-favorable HL	Combined modality therapy • 2–4 cycles of chemotherapy followed by involved-field radiotherapy
Early-unfavorable HL (intermediate-stage)	Combined modality therapy • 4–6 cycles of chemotherapy followed by involved-field radiotherapy
Advanced HL	Extensive chemotherapy • 6–8 cycles of chemotherapy ± consolidation with localized radiotherapy

HL, Hodgkin lymphoma.

chemotherapy followed by 20 Gy as a standard approach in this group of favorable patients.[34] Subsequently, the HD13 study evaluated the elimination of bleomycin and dacarbazine in the ABVD regimen when given in combination with IRFT but demonstrated high rates of treatment failures with the omission of agents.[35]

In unfavorable early-stage patients, with the exception of the combination of bulky disease and B symptoms, the GHSG HD11 trial randomized 1397 patients between 4 cycles of ABVD and 4 cycles of baseline BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisolone), and each chemotherapy arm was followed by either 30 Gy or 20 Gy IFRT.[36] Four cycles of ABVD followed by IFRT of 30 Gy resulted in a 5-year FFTF of 85.3% and OS of 94.3% and was less toxic than baseline BEACOPP. In the subsequent trial, HD14, 2 cycles of escalated BEACOPP followed by 2 cycles of ABVD and 30 Gy IFRT (HD14 trial) was compared to 4 cycles of ABVD and IFRT. Although the FFTF was superior in the escalated BEACOPP arm at 95% versus 88% there was no difference in OS with median follow-up of 43 months. Toxicity in the intensified regimen was significant particularly in terms of myelosuppression and infection, and there were two cases of myelodysplastic syndrome (MDS)/acute myeloid leukemia (AML).

Given the risk of late toxicity associated with RT, the Canadian/ECOG HD6 study evaluated the use of chemotherapy alone in early stage HL in 405 patients.[37] The study which employed subtotal nodal radiation therapy (STNRT) was closed early after this approach was replaced by IRFT based on clinical trial results published during the course of the study. Patients with stage I-IIA disease treated in the experimental arm received 4 cycles of ABVD if interim CT scans demonstrated complete remission and all others were treated with 6 cycles. Patients in the standard arm with no risk factors were treated with STNRT and unfavorable disease defined as age greater than 40, great than four lymph node sites involved, presence of mixed cellularity or LD histology, ESR greater than 50, received STNRT plus 2 cycles of ABVD. With median follow-up of 11.3 years, freedom from disease progression was 87% in the chemotherapy only group versus 92% in those receiving RT. The 12-year OS rate, however, was superior at 94% in the chemotherapy only group compared to the 87% in those receiving RT. STNRT used in the study is likely associated with increased risk of late toxicity compared to modern RT approaches. Despite this, the study led to the increased use of chemotherapy alone, particularly in younger women with increased risk of breast cancer and others at higher risk for late adverse effects.

Radiation Therapy Planning and Treatment

Modern RT techniques for planning and treatment have significantly decreased the risk of side effects. The radiation fields using ISRT, based on published guidelines by the International Lymphoma Radiation Oncology Group (ILROG),[38,39] has educated radiation oncologists on how to target the sites of the disease while avoiding the surrounding normal tissues. Advances in computer-based planning, inverse planning technology (using mathematical iterations for planning with Intensity Modulated Radiation Therapy, IMRT) and proton therapy are now considered standard treatment.[40] Real-time verification of radiation delivery using onboard imaging increased the refined targeting of radiation. Finally, ILROG guidelines gives elaborate recommendations as to how to respect normal tissues tolerance, strict constraints to be applied to protect the heart, coronary vessels, breasts, lungs, thyroid, kidneys, and salivary glands.

Response-Adapted Treatment Approach

More recently, in the era of FDG-PET imaging for assessment of metabolic response to induction chemotherapy, risk adapted approaches have been tested in a number of clinical trials.[32,41] The EORTC H10 trial, which used modern- INRT techniques, randomized (both favorable and unfavorable risk) patients to chemotherapy alone (4 cycles total in the favorable and 6 cycles in the unfavorable) versus combined modality treatment (CMT) for those with a negative FDG-PET after 2 cycles of ABVD.[42] The outcomes were excellent in patients who received chemotherapy alone or CMT. This study enrolled 1137 patients and after 34 events, per study design, the interim analysis mandated closure of the chemotherapy only arms given excess relapse rates. Overall, approximately 81% of patients were PET2 negative. In the favorable group, the 5-year PFS was 99% in the CMT arm compared to 87% in the chemotherapy alone arm. The difference was less pronounced in the unfavorable arm at 92% versus 90% respectively. The addition of RT did not translate into an OS benefit. For the PET positive patients, 5-year PFS was 91% with escalation to BEACOPP plus INRT compared to 77% in the ABVD + INRT arm. There was a trend for improvement in OS in the intensified arm at 96% versus 89.3% with HR 0.4 ($P = .062$).[42]

The UK National Cancer Research Institute (NCRI) RAPID trial also tested a PET adapted strategy in early-stage HL patients.[26] 420 PET-negative patients (after 3 cycles of ABVD) were randomized to receive IFRT versus no further treatment. After a median follow-up of 45 months, this noninferiority trial revealed no difference in OS, but slightly, although not statistically significant, higher 3-year PFS (intention to treat analysis) in patients receiving IFRT (93.8% versus 90.7%), where a margin of ≤7% PFS difference was deemed acceptable.[5] When an “as-treated” analysis was performed, the 3-year PFS was 97% for CMT versus 90.7% for chemotherapy alone (hazard ratio [HR] = 2.39, $P = .03$).

In the HD16 GHSG study of patients with early favorable disease ($n = 1150$), patients were randomly assigned to standard therapy with 2 cycles of ABVD plus 20 Gy IFRT versus PET guided therapy.[43] PET2 negative patients received no further therapy. In PET2 negative patients ($n = 628$), 5-year PFS was 86% versus 93% in the chemotherapy only and CMT arms respectively. For patients treated with standard therapy the 5-year PFS was 93% in the PET2 negative and 88% in the PET2 positive groups.

In a US non-randomized PET directed study of 164 patients with early favorable and unfavorable patients without bulky disease, the Alliance cooperative group instead chose to administer 4 cycles of ABVD to PET2 negative patients.[27] PET2 positive patients were treated with 2 cycles of escalated BEACOPP plus IFRT. 91% of patients were PET2 negative with 3-year PFS of 91% (94% in those with Deauville scores of 1 to 2 and 77% in the Deauville 3 group). In the PET2 positive arm, the 3-year PFS was 66%.

TREATMENT OF ADVANCED-STAGE HODGKIN LYMPHOMA

The improved outlook for patients with advanced-stage HL (stages IIB–IV) over recent decades is largely attributed to the global drive to develop front-line chemotherapy regimens in which improved efficacy is coupled with reduced treatment-associated toxicity. Today, the most widely used regimens are ABVD (adriamycin, bleomycin, vinblastine, and dacarbazine), BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisolone) and AAVD (Adriamycin, brentuximab vedotin (Adcetris), vinblastine and dacarbazine) (Table 80.6).

ABVD

The ABVD regimen was developed in 1975 as a salvage regimen for patients with relapsed HL.[44] Subsequently, ABVD became a standard first-line therapy based on several randomized trials establishing its safety and efficacy (see Table 80.6). Although one of the main attractions of ABVD is its ability to maintain excellent OS without unnecessarily exposing the patient to the toxicity associated with alkylating agents, bleomycin-induced pulmonary toxicity remains an important problem for some individuals. The introduction of interim PET scanning in recent years has significantly reduced the use of bleomycin. The UK NCRI RATHL trial established that in those patients who had a negative PET scan (defined as a Deauville score of 1 to 3, Table 80.7) after 2 cycles of ABVD, 4 cycles of AVD were as effective and less toxic than 4 cycles of ABVD.[45] The 3-year PFS for interim PET negative patients in the ABVD arm was 85.7 (95% CI: 82.1% to 88.6%) compared with 84.4% (95% CI 80.7% to 87.5%) for those treated with AVD.[7]

A recent modification of the ABVD regimen has been to replace bleomycin with the anti-CD30 antibody drug conjugate Brentuximab vedotin (BV). Initially, BV was combined with standard ABVD in a phase-I trials, but this combination was associated with a high frequency of lung toxicity.[46] However, when bleomycin was omitted from the regimen, BV + AVD demonstrated no significant lung toxicity while maintaining its efficacy.[46–48] These encouraging results were the basis for a randomized phase 3 trials comparing standard 6 cycles of ABVD with 6 cycles of BV+AVD.[48] The 2 year modified PFS was 77.2% (95% CI: 73.7% to 80.4%) with ABVD and 82.4% (95% CI 78.8% to 85%) with AVD+BV.

TABLE 80.6 Standard Chemotherapy Regimens for the Treatment of Advanced Hodgkin Lymphoma

Regimen	Drugs	Route	Schedule
ABVD	Adriamycin 25 mg/m^2	IV	Day 1 and 15
	Bleomycin 10 mg/m^2	IV	Day 1 and 15
	Vinblastine 6 mg/m^2	IV	Day 1 and 15
	Dacarbazine 375 mg/m^2	IV	Day 1 and 15
			Every 28 days
BEACOPP (escalated)	Bleomycin 10 mg/m^2	IV	Day 8
	Etoposide 200 mg/m^2	IV	Day 1–3
	Adriamycin 35 mg/m^2	IV	Day 1
	Cyclophosphamide 1250 mg/m^2	IV	Day 1
	Vincristine 1.4 mg/m^2	IV	Day 8
	Procabazine 100 mg/m^2	PO	Days 1–7
	Prednisolone 40 mg/m^2	PO	Days 1–14
	G-CSF	SC	From day 8
			Every 21 days
A2VD (AVD with Brentuximab vedotin)	Adriamycin 25 mg/m^2	IV	Day 1 and 15
	Brentuximab vedotin 1.2 mg/kg	IV	Day 1 and 15
	Vinblastine 6 mg/m^2	IV	Day 1 and 15
	Dacarbazine 375 mg/m^2	IV	Day 1 and 15
	G-CSF	SC	
			Every 28 days

G-CSF, Granulocyte colony-stimulating factor.

BEACOPP

In 1992, the GHSG conducted a pilot study investigating whether treatment response and outcome could be improved by dose intensification in patients with newly diagnosed advanced HL. The BEACOPP regimen (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisolone) was developed with encouraging results in preliminary studies. In a subsequent randomized HD9 trial, standard-dose BEACOPP and escalated BEACOPP regimens were compared with COPP/ABVD.[49] The best results were achieved with escalated BEACOPP (OS 91% escalated BEACOPP vs. 88% standard BEACOPP vs. 83% COPP/ABVD, $P < .002$). The rate of early progression was also significantly lower in the escalated BEACOPP arm (2% escalated BEACOPP vs. 8% standard BEACOPP vs. 10% COPP/ABVD, $P < .001$). Because of the superior outcomes observed with both BEACOPP regimens, the COPP/ABVD arm in this study was closed at interim analysis. The improved outcome seen with escalated BEACOPP in the HD9 study was substantiated by long-term follow-up analysis at 10 years.

Despite the success demonstrated by escalated BEACOPP in the HD9 trial, longer-term complications including the development of myelodysplastic syndrome and secondary acute myeloid leukemia (AML) occurred more frequently when compared with standard BEACOPP and COPP/ABVD.[49,50] In addition, acute hematologic toxicity, including anemia and thrombocytopenia, was also greater in the escalated BEACOPP arm, with blood product support being required more frequently. The increased toxicity observed with escalated BEACOPP provided the rationale for the GHSG to investigate the efficacy and toxicity of lower doses of BEACOPP but given every 14 days, in a time-intensified manner (BEACOPP-14) and of reducing the number of cycles of escalated BEACOPP. This led to a multicenter, noninferiority randomized study (HD15 trial) in which 2182 patients with newly diagnosed advanced HL, aged between 18 and 60 years, were assigned to receive either 8 cycles of escalated BEACOPP, 6 cycles of escalated BEACOPP, or 8 cycles of BEACOPP-14, followed by PET-directed RT.[51] FFTF at 5 years was sequentially superior with 6 cycles of escalated BEACOPP (89.9%) compared to 8 cycles of BEACOPP-14 (85.4%) and with 8 cycles of escalated BEACOPP (84.4%). OS with 6× escBEACOPP was also superior that 8× escBEACOPP (95.3% for 6× escBEACOPP vs. 91.9% for 8× escBEACOPP).[51]

TABLE 80.7 Deauville 5-Point Scale for the Interpretation of Interim and End of Treatment FDG-PET Imaging in Patients With Hodgkin Lymphoma

FDG-PET Uptake	Deauville Score
No uptake above background	1
Uptake equal to or below mediastinum	2
Uptake higher than mediastinum but equal to or lower than liver	3
Uptake moderately higher than liver	4
Uptake significantly higher than liver and/or presence of new lesions	5
New areas of uptake/new FDG-PET avid lesions	X

FDG-PET, Fluorodeoxyglucose-positron emission tomography.

Furthermore, 8 cycles of escalated BEACOPP was associated with a higher mortality rate when compared to 6 cycles of escalated BEACOPP (7.5% vs. 4.6%, respectively), as well as an increased frequency of secondary malignancies (1.8% vs. 1.1%, respectively). It was concluded that overall, in patients younger than 60 years, 6 cycles of escalated BEACOPP followed by PET-directed RT was more effective and less toxic.

More recently, the HD18 trial compared PET directed therapy to further reduce the cycle number of escBEACOPP, with a standard 8 cycles of escBEACOPP (which was reduced to 6 cycles during the trial, when the HD15 results became known).[52] In this study, all patients with advanced HL received 2 cycles of escBEACOPP followed by a PET-CT scan. Patients with a negative scan (defined as a Deauville score of 1 and 2) were randomized to receive only 2 more cycles or 4 to 6 more (initially 6 but then reduced to 4 later in the trial) whereas those with a positive PET-CT were randomized to receive a full 6 to 8 cycles of escBEACOPP with or without rituximab. Rituximab use was not associated with significant differences in outcomes. In the interim PET negative group, 4 cycles of escBEACOPP in total was associated with a similar 5-year progression free survival (90.8% (95% CI: 87.9% to 93.7%) compared to 6 to 8 cycles (92.2% (89.4% to 95% for 4 cycles).[52]

ABVD Versus Escalated BEACOPP

ABVD and escalated BEACOPP are internationally accepted as appropriate first-line treatments for patients with newly diagnosed advanced HL, but which of these approaches is optimal remains under debate. Although ABVD is more widely used in the Unites States, escalated BEACOPP tends to be the more favored approach in many parts of Europe.

A number of studies have directly compared these two regimens with different approaches. A randomized study carried out by the EORTC in 2012 investigated whether patients with high-risk advanced disease (IPS ≥ 3) were likely to achieve greater benefit with a more intensive upfront regimen comprising 4 cycles of escalated BEACOPP followed by 4 cycles of standard BEACOPP or 8 cycles of ABVD.[53] There was no significant difference in event-free survival (EFS) or OS between the two treatment groups.[53] Relapse rates were higher with ABVD, but the frequency of early discontinuations was greater with escalated BEACOPP. In a parallel study investigating the same two regimens but in patients with advanced HL with lower-risk (IPS 0 to 2), the PFS was significantly better in the BEACOPP arm (93% vs. 75%, $P = .007$), but with no significant OS advantage (99% vs. 92%, $P = .06$). Again, fewer relapses were observed with BEACOPP.[54]

RELAPSED AND REFRACTORY HODGKIN LYMPHOMA

Although the vast majority of patients with newly diagnosed HL achieve a remission after first-line therapy, around 10% will have refractory disease (defined as progression or nonresponse during initial treatment or within 90 days of completing treatment). In addition, of those achieving initial cure, approximately 30% will relapse. Further remissions can be achieved for these patients with salvage therapy, for which the optimal choice depends on a combination of factors including the patient' s stage of disease at relapse, their prior therapies, and their risk factor profile.

Prognostic Factors in Relapsed or Refractory Hodgkin Lymphoma

A number of risk factors for refractory disease or relapse following initial therapy have been identified for patients with HL. In two large retrospective analyses conducted by the GHSG, poor performance score at the time of progression, age greater than 50 years, and failure to achieve a temporary remission on first-line treatment were highlighted as significant predictors of adverse outcome for patients with primary refractory HL: in addition, time to first relapse, clinical stage III or IV disease at relapse, and anemia (hemoglobin <12 g/L males or <10.5 females) were considered significant predictors of adverse outcome for patients with relapsed HL. Of these prognostic factors, performance status at relapse, advanced stage at relapse, and time to relapse appear to be consistently associated with poor risk across studies, but prospective confirmation of these is still needed.

Treatment of Relapsed or Refractory Hodgkin Lymphoma

Salvage Chemotherapy and Autologous Stem Cell Transplant

The treatment of choice for the majority of patients with relapsed HL, or with refractory disease that has not responded to initial chemotherapy, is cytoreduction with salvage chemotherapy followed by high-dose therapy and autologous stem cell transplant (ASCT).

The goal of cytoreduction with salvage chemotherapy and preparative high dose chemotherapy before ASCT is to achieve high response rates and a minimal disease state, while maintaining an acceptable toxicity profile, without compromising subsequent stem cell mobilization and engraftment. A number of second-line salvage chemotherapy combinations are currently in use, but because of a lack of randomized data comparing these regimens, there is no consensus as to which is optimal. Common regimens include DHAP (dexamethasone, cisplatin, cytarabine), ICE (ifosfamide, carboplatin, etoposide), GVD (gemcitabine, vinorelbine, liposomal doxorubicin), and ESHAP (etoposide, methylprednisolone, cytarabine, cisplatin), with patients typically receiving 2 to 3 cycles of therapy before proceeding to ASCT.[55–58]

The advantage of ASCT over standard chemotherapy alone has been demonstrated in a number of studies. In 1997, Yuen and colleagues compared the outcome of patients receiving high-dose etoposide, cyclophosphamide, and total body irradiation (TBI) or carmustine followed by ASCT, with a matched conventional salvage group who received chemotherapy alone.[59] At 4 years of follow-up a clear improvement was seen in those who underwent transplant with regards to OS, EFS, and FFP over chemotherapy alone (OS 54% vs. 47%, $P = .25$; EFS 53% vs. 27%, $P < .01$, FFP 62% vs. 32%, $P < .01$).

Two key randomized control trials have supported the superior role of ASCT over conventional salvage therapy and have been integral to establishing this approach as the standard of care for patients with relapsed or refractory HL: In a comparison of high-dose BEAM chemotherapy plus autologous transplant versus standard-dose mini-BEAM chemotherapy alone, the British National Lymphoma Investigation (BNLI) group demonstrated significant differences in EFS and PFS in favor of BEAM followed by autologous transplant (53% vs. 10%).[60] In a larger trial conducted by the GHSG/EBMT, 161 patients with relapsed or refractory HL were chosen at random to receive either 4 cycles of dexa-BEAM or 2 cycles of dexa-BEAM, followed by 2 further cycles of high-dose BEAM and ASCT. In chemosensitive patients, FFTF at 3 years was significantly better for those proceeding to HDCT and ASCT (55%) compared to standard chemotherapy alone (34%, $P = .019$), although there was no significant difference in OS between the two groups.[61]

Treatment Post Autologous Stem Cell Transplant

Three drugs have been approved by the US Food and Drug Administration (FDA) for the treatment of patients with relapsed HL after receiving ASCT; brentuximab vedotin, and two check point inhibitors, pembrolizumab and nivolumab.

Brentuximab Vedotin

The cell surface antigen CD30 is highly expressed on Hodgkin and Reed-Sternberg (HRS) cells.[62] The efficacy of agents targeting CD30 has been extensively investigated for patients with relapsed and refractory HL. Brentuximab vedotin (SGN-35) is an antibody-drug conjugate (ADC) comprising an anti-CD30 monoclonal antibody conjugated to antitubulin monomethyl auristatin E (MMAE).[63]

An initial phase I dose-escalation study in patients with relapsed or refractory CD30-positive hematologic cancers showed that BV is associated with a favorable safety profile and established 1.8 mg/kg every 3 weeks as the MTD. Significant efficacy was also observed in this study: tumor regression was demonstrated in 86% of patients, with a median durable response of 9.7 months.[64] In a pivotal phase II trial of 102 patients with CD30-positive relapsed or refractory HL who had failed ASCT the safety and efficacy of BV was evaluated further.[65] Overall response rate (ORR) was 75%, with 34% of patients achieving a complete response. The median duration of response was 20.5 months. Peripheral neuropathy, nausea, fatigue, neutropenia, and diarrhea were the most common treatment-related toxicities. As a result of this study, in 2011 BV was the first drug to be approved by the US FDA for the treatment of patients with relapsed or refractory HL following ASCT. BV was also evaluated as maintenance therapy following ASCT and was shown to significantly improve PFS compared to placebo in patients with high-risk relapsed or refractory HL.[66]

Checkpoint Inhibitors

PD-1 (programmed cell death protein 1) is a cell surface receptor that is expressed on T regulatory and activated T cells (CD4 and CD8), activated B cells and natural killer (NK) cells. PD-1 binds PDL-1 and PDL-2, two ligands that are expressed by antigen-presenting cells and several cancer cells, including RS cells in HL (see Fig. 80.5).[16,67] The PD-1/PDL-1/2 interaction inhibits kinases that are normally involved in T-cell activation. In this way the PD-1 pathway serves as a checkpoint to restrict T-cell–mediated immune responses, enabling tumor cells to evade immune detection. Inhibitors of PD-1, which block PD-1/PDL-1/2 engagement, may enhance T-cell immunity and prevent immune evasion by tumor cells, leading to effective cancer cell death.[68]

Remarkable single-agent activity in patients with relapsed HL has been reported with either monoclonal antibody directed against PD-1 nivolumab or pembrolizumab.[69,70] ORR is around 65% for either agent, with CR rate relatively low. Both agents are approved by the FDA for the treatment of relapsed and refractory HL.[69–71] Accordingly, anti-PD1 antibodies are investigated in combination with multiple regimens with promising activity. In particular, the combination of nivolumab and brentuximab vedotin showed a high ORR of 82% and CR rate of 61% in a second-line pre-transplant setting.[72]

SPECIAL CONSIDERATIONS

Hodgkin Lymphoma in the Elderly

The number of patients living with cancer over the age of 60 years is increasing. The outcome of elderly patients with HL may differ significantly because of the heterogeneity of this population with regards to life expectancy, premorbid performance status, and comorbidity. Establishing optimal treatment is therefore challenging, particularly because older patients do not tend to be well-represented in large clinical trials caused by tight exclusion criteria that often render them ineligible for enrollment. Data, therefore, are not necessarily representative of the general elderly population.[73]

In a comprehensive retrospective analysis of 4251 patients with HL, acute treatment-related toxicity was higher in older patients compared with those under the age of 60 years. In addition, elderly patients with HL had a worse outcome with respect to freedom from treatment failure (60% vs. 80%) and OS (65% vs. 90%), which was attributed to both increased mortality during treatment as well as the fact that significantly fewer elderly patients were able to tolerate the intended full dose of therapy (75% vs. 91%).[74]

It is recommended that elderly patients without significant comorbidity and with a good performance status should be treated according to the current standard of care for younger individuals, on a risk-adapted basis, according to stage, with curative intent. Treatment-related toxicity and mortality may, however, occur more frequently.[75,76]

Hodgkin Lymphoma During Pregnancy

Given that the early incidence peak of HL coincides with childbearing age its management during pregnancy should assume special consideration. Lymphoma is the fourth commonest malignancy presenting in pregnancy and, of these, HL occurs most frequently. The diagnosis of HL during pregnancy matches that of the background population; lymph node biopsy can be performed safely either under local or general anesthetic. Clearly, however, traditional staging methods for patients with newly diagnosed HL who are pregnant need to be adapted.[77] To avoid the risks associated with radiation exposure to the fetus, radiologic evaluation via chest X-ray with abdominal shielding, abdominal ultrasound, or magnetic resonance imaging, is recommended rather than CT or PET. Routine blood work and bone marrow biopsy are also indicated, as per standard practice. This modified approach to staging during pregnancy is considered sufficient to allow appropriate ongoing management decisions, at least until more comprehensive imaging can be completed following delivery.

Consensus regarding the optimal treatment for pregnant patients with HL varies. The risk of spontaneous abortion and congenital malformations secondary to cytotoxic treatments and/or RT is known to be highest in the first trimester. Although risk decreases as pregnancy continues, the exact extent of risk during this period has not been clearly established and long-term complications are unknown. This is largely caused by the lack of data that exists as a result of small patient numbers. Thus, whether chemotherapy should be started or not during pregnancy requires cautious evaluation of the risks to the unborn fetus versus the risks to maternal survival as a result of postponing treatment. Low-risk, asymptomatic patients may be monitored closely, with treatment being delayed until either the end of the first trimester or until delivery if diagnosis occurs later on during the pregnancy. For patients with bulky or symptomatic disease that requires treatment, however, single agent anthracyclines or vinca-alkaloids are deemed acceptable first choices, escalating to combined chemotherapy, usually with ABVD, following delivery or during the second or third trimester if there is evidence of progressive disease. In this latter subgroup of patients, however, the option of therapeutic abortion should be discussed with the patient and family to ensure all decisions made are informed.

LONG-TERM COMPLICATIONS OF TREATMENT IN HODGKIN LYMPHOMA

The high cure rate associated with HL translates to a significant proportion of patients who are at an increased risk for a range of long-term sequelae of treatment. Data on the cumulative incidence of cause-specific mortality in HL survivors show that although the rate of lymphoma-related deaths plateaus after the first 10 to 15 years following therapy, the rate of death because of late complications continues to rise.[78,79] The significance of long-term sequelae following treatment for HL has become more apparent over recent years given the growing number of young survivors.[80] However, it is important to remember that a significant proportion of the data surrounding late effects relate to patients who were treated with chemotherapy and RT approaches that no longer feature in current practice. Increased awareness of long-term complications can account for many of the important treatment modifications which have been made over the past two decades, and provides the current rationale for ongoing development with regards to novel agents as well as RT technique. Current and future follow-up approaches for these individuals requires vigilance, focusing on strategies that enable both early detection and primary prevention wherever possible for the impact of these sequelae to be reduced.[81]

The management of late toxicities associated with chemotherapy and/or RT is often more challenging than acute, with effects in some cases being irreversible and life threatening. Long-term treatment-related complications in patients previously treated for HL include hypothyroidism, peripheral neuropathy, gonadal dysfunction, secondary malignancy, and cardiovascular disease. Of these, secondary malignancy and cardiovascular complications occur most frequently, with risk continuing even beyond 25 years from diagnosis, and represent the two most common entities determining quality of life: long-term morbidity and mortality in this patient population.

It is well described that intensive RT with extended field size and certain chemotherapy agents, such as cyclophosphamide, nitrogen mustard, procarbazine, and etoposide may increase the risk of developing secondary malignancies. Solid tumors appear to account for the majority of cases of secondary malignancy, with breast cancer, lung cancer, and gastrointestinal cancer occurring most frequently.[78,79] This risk has been shown to be significantly greater among patients treated for HL during childhood or during teenage years. Among the female population, secondary breast cancer predominates, with extended radiation field size and the administration of RT to those under the age of 30 years representing the two most significant risk factors. The time to develop breast cancer is usually about 10 to 15 years. Therefore, for all female patients receiving radiation to the mediastinum or axillae, annual breast screening with mammography is recommended 8 to 10 years after treatment or from the age of 40 years, whichever occurs first.

The risk of secondary hematologic malignancy, including leukemia and myelodysplasia, has been particularly associated with prior exposure to alkylating chemotherapy, especially when delivered in combination with large-field RT. Although this risk has fallen with the use of more modern chemotherapy, the exact choice of regimen still appears to be significant, with the incidence of AML or myelodysplasia being significantly greater among those treated with more intensive chemotherapy, such as BEACOPP, than with ABVD. The time to develop treatment-related leukemia after HL is about 3 to 5 years, and the prognosis of these patients is poor, with an estimated OS of 7.2 months.

The risk of cardiovascular disease may be three- to fivefold increased in survivors of HL compared with the general population. Cardiac complications tend to present themselves approximately 10 to 15 years after exposure, although the actual disease onset may in fact be well before this, given the lack of early symptoms in many cases.[79,82,83] The association between anthracycline-based chemotherapy and cardiac toxicity is well established and is particularly relevant to the setting of HL given the chemotherapy combinations currently used in standard practice. Anthracycline-induced cardiac toxicity typically manifests as arrhythmias or congestive cardiac failure as a result of ventricular dysfunction secondary to direct myocardial damage. The severity of cardiac toxicity is directly correlated to the cumulative dose that is delivered and, as such, both individual dosages and the number of cycles are significant considerations when planning treatment. Radiation exposure has also been implicated in the development of late cardiac diseases including coronary artery disease, valvular dysfunction, myocardial dysfunction, pericarditis, and conduction defects, and radiation-related cardiac toxicity remains a major factor compromising overall outcome in HL survivors. Optimal screening methods for cardiovascular disease are not clearly established and therefore close monitoring of these patients is warranted, including strict control of cardiac risk factors (including hypertension, diabetes, hypercholesterolemia, and smoking).

A number of agents used in the treatment of HL can result in gonadal dysfunction, which is of particular relevance given the young age of this patient population.[84] Pelvic RT and intensive alkylating-based frontline chemotherapy regimens such as MOPP and escalated BEACOPP have been shown to induce male and female sterility whereas the risk is reduced with baseline BEACOPP and reduced even further with less aggressive combinations such as ABVD where it is usually only transient. Unsurprisingly, however, the risk rises significantly among patients with relapsed or refractory disease following high-dose salvage chemotherapy. It is therefore recommended that all patients with newly diagnosed HL, who are of reproductive age, should be offered fertility preservation before commencing therapy.

CHAPTER 81

ORIGIN OF NON-HODGKIN LYMPHOMA AND THERAPEUTIC TARGETS

Matthew S. McKinney and Sandeep S. Dave

Over the past two decades, discoveries in basic immunology and the pathogenesis of malignancies have significantly advanced our understanding of the origin of lymphoid neoplasms. These diseases have been reexamined and grouped based on recurrent chromosomal rearrangements, histologic patterns, gene expression profiles, and more recently by patterns of gene mutations, gene fusions, and epigenetic alterations. The multiple revisions to the World Health Organization's classification schemes for lymphomas reflect our evolving understanding of groupable lymphoma subtypes. As with other cancers, lymphoma development is dependent upon acquisition of mutations, DNA copy number changes, recurrent cytogenetic rearrangements, and epigenetic dysregulation of gene expression involving oncogenic and tumor suppressor pathways. Many of these derangements occur as a result of disordered genetic recombination and somatic hypermutation (SHM) events intended to support adaptive immunity. Also, analysis of molecular features of lymphomas compared to normal lymphocyte compartments provides clues to the events driving their pathogenesis.

An evolving understanding of the steps involved in lymphoid development has provided further insights into the development of this diverse group of malignancies because most non-Hodgkin lymphomas (NHLs) reflect stages of lymphoid development. The application of gene expression profiling (GEP) and massively parallel high-throughput sequencing, as well as a better appreciation of the contribution of microRNAs (miRNAs) and epigenetic alterations to lymphoma pathogenesis, have shed new light on the mechanisms underlying lymphomagenesis. Understanding of clinical and epidemiologic features of non-Hodgkin lymphomas provides additional insight into the origin of these malignancies. In this review, we emphasize that a collaboration of genetic alterations (some of which are induced by the unique biology of the adaptive immune system) collaborated with host features including immune stimulation and lack of tumor surveillance to drive the formation of lymphomas that mirror the phenotypic characteristics of their underlying cell of origin (this can be conceptualized as in Fig. 81.1).

This chapter reviews the most common NHL subtypes, focusing on common B-cell lymphoma subtypes, with regard to classification using prevailing views regarding genetic or genomic classification of these disorders. Additionally, insights regarding pathogenesis, prognosis, and possible therapeutic targets gleaned from genomic approaches are discussed.

OVERVIEW OF B-CELL LYMPHOMAS

Greater than 85% of NHL cases have a B-cell phenotype. With rare exception, B-cell lymphomas represent immortalized, "frozen" stages of B-cell development and the underlying molecular features of B-cell tumors reflect biologic features found in analogous normal B-cell compartments. Understanding that regulation of B-cell compartments that mirror B-cell NHL subtypes is thus crucial to understanding the driving forces behind lymphoma development (Fig. 81.2).

The goal of early B-cell development is to produce mature B cells expressing surface immunoglobulin M (IgM) that can efficiently recognize cognate antigen. After this is accomplished, B cells develop along pathways involving germinal center (GC), mantle, and marginal zones in lymphoid organs where they encounter antigen in association with activated antigen-presenting cells (APCs). Differentiation of mature B cells into plasma cells after SHM is the final step in B-cell development and is critical to the development of effective humoral immunity. Antibody diversity is accomplished through the process of somatic V(D)J recombination at the pro–B-cell stage via recombinase activating genes (*RAG1* and *RAG2*) followed by trafficking to GCs, where they proliferate rapidly with dividing times of 6 to 8 hours. High-affinity B-cell clones produced in part via activation-induced cytidine deaminase (AID) expression and SHM are favored because of protection from apoptosis. Through this mechanism, protective antibodies are produced at the risk of exposing antigen-stimulated B cells to genetic lesions caused by the molecular machinery utilized to create V(D)J recombination and SHM. Many NHLs exhibit translocations of driver oncogenes to highly active Ig loci, implying that recombination events intended to produce high-affinity antibodies are misdirected and instead produce immortalized B cells representing stages of B-cell development. Furthermore, mutations in oncogenes or tumor suppressors frequently occur in a pattern consistent with SHM at these loci. When considered together with the recurrent chromosomal rearrangements noted in NHL, this confirms the notion that these neoplasms stem from mature B cells that have entered (or are poised to enter) GCs.

Subsets of NHL recapitulate this pattern of normal B-cell differentiation at the histologic, molecular, and genomic levels and serve as a template for the classification of these diseases. This template can be applied to the entire spectrum of B-cell neoplasms, suggesting that NHLs form as a result of genetic alterations developed along this process. B-cell differentiation must be carefully choreographed at the molecular and genomic level because the expression of the *RAG* genes and AID cause DNA strand breaks and put the nascent lymphocyte at risk of oncogene overexpression and tumor suppressor deletion. Moreover, a coordinated regulation of gene expression is required to allow such genomic revision without triggering reflexive, protective apoptotic pathways and to allow appropriate B-cell differentiation. GC B cells highly express BCL6, and its functions are critically important to regulation of cell survival and differentiation. Targets of BCL6 also include cell cycle regulators (p21, p27) and TP53, which may overall work to facilitate cell cycle progression in the face of ongoing AID-mediated DNA strand breaks. BCL6 also represses *PRDM1*/Blimp1 and serves to prevent plasmacytic differentiation. Plasma cell differentiation is mediated by upregulation of IRF4 and nuclear factor kappa-B (NFκB), which establish characteristic regulatory programs.

Genetic lesions altering these pathways are found recurrently in NHL. *BCL6* rearrangements occur in diffuse large B-cell lymphoma (DLBCL) and other lymphomas, and constitutively active NFκB signaling is associated specifically with aggressive phenotypes of DLBCL. Translocations and or mutations of *BCL2*, which is expressed at very low levels in GCs, occur in almost all follicular lymphomas (FLs) and illustrate the dangers of aberrant recombination events in the GCs because *BCL2* translocation appears to be a primary event in the formation of these tumors. Recent analyses of whole genome/exome/transcriptome sequencing data have confirmed the frequent presence of these genetic lesions and have illuminated other pathways driving lymphomagenesis. In GC-derived B-cell lymphomas, mutations in *EZH2*, a member of the polycomb group (PcG), occur frequently. In

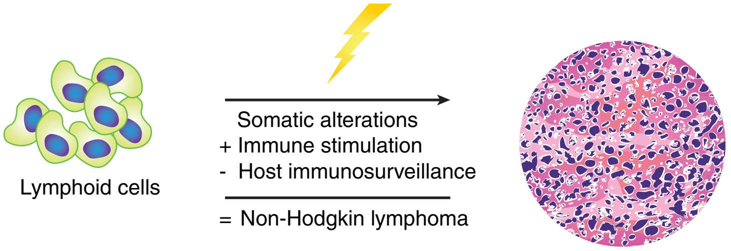

Figure 81.1 SCHEMATIC FOR COLLABORATION OF DNA DAMAGE/GENOME INSTABILITY AND IMMUNE STIMULATION. Non-Hodgkin lymphoma formation depends on several features that results in the transformation of normal lymphoid tissues to malignant lymphoma.

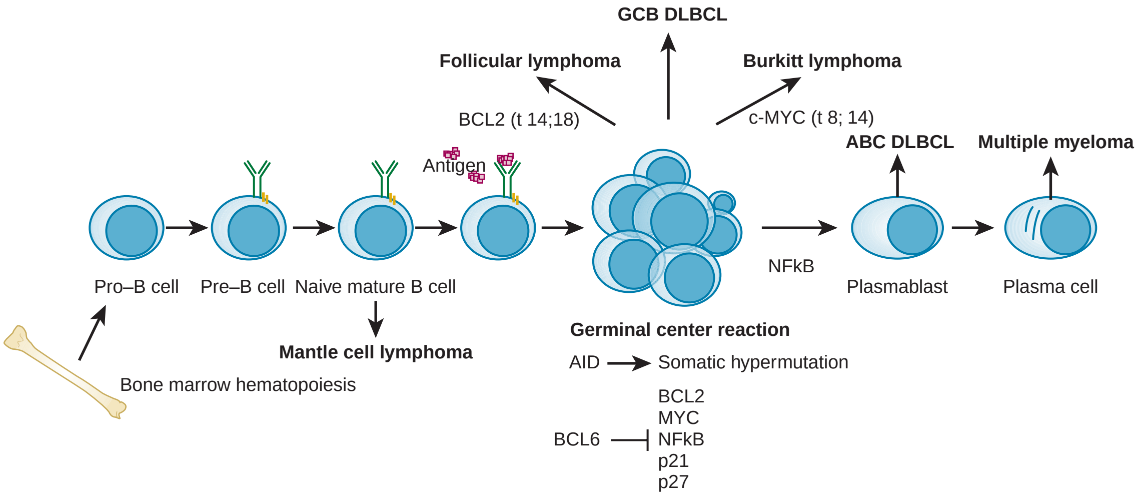

Figure 81.2 CLASSIFICATION OF COMMON NON-HODGKIN LYMPHOMAS (NHLs) IN RELATION TO B-CELL DEVELOPMENT IN GERMINAL CENTERS (GCs). Hematopoiesis results in B-cell precursors that ultimately produce immunoglobulin M (IgM) that recognizes cognate antigen via activation of recombinase activating genes (*RAG1* and *RAG2*) and a GC reaction occurs. A regulatory program relying on BCL6 regulation of cell proliferation and apoptosis occurs at this point, and rearrangements presumed to occur along this course result in post-GC lymphomas, including follicular lymphoma, Burkitt lymphoma, and diffuse large B-cell lymphoma (DLBCL). The underlying molecular biology of NHL subsets (and other lymphoid neoplasms) reflects the GC step and other stages of B-cell development. For example, gene profiling of DLBCL reveals that whereas activated B-cell–like (ABC) DLBCL reflects the plasmablast stage along normal B-cell development, multiple myeloma expression profiles more consistent with differentiated plasma cell origin.

these tumors, EZH2 mutations result in aberrant histone methylation with resultant dysregulated control of gene expression and result in GC hyperplasia in mouse models. This process appears to enhance lymphomagenesis due to an acquired inability of GC B cells to differentiate and appropriately complete maturation and thus become transformed in a state of reflecting GC B cells (Fig. 81.3). A similar role for GC regulation has been defined for genes in the sphingosine-1-phosphate receptor2 (S1PR-2) signaling pathway. Genes encoding mediators of this pathway such as *S1PR2*, *P2RY8*, and *GNA13* are frequently mutated in GC B-cell–derived lymphomas and result in dissemination of GC cells within lymph nodes. Thus, derangements in several different genes can result in abnormal GC homeostasis and drive lymphoma formation; this is a novel paradigm whereby dysregulation of B-cell differentiation leads to transformation and lymphoma.

Regulation of antigen stimulation of the B-cell receptor (BCR) is also important in both B-cell maturation and the development of NHL. The BCR consists of a multimeric signaling complex, including CD79A and CD79B, which acts through the immunoreceptor tyrosine activation motif on CD79B and leads to a cascade of molecular events involving SYK and BTK signaling. The end result of this cascade is an increase in cellular proliferation through activation of NFκB target genes and other cellular machinery. Almost all NHLs express surface Ig, suggesting that functional BCR signaling is important at some point in the process of lymphoma formation. Analysis of Ig SHM patterns in lymphoma samples further suggests that antigen-induced selective pressure is important in the pathogenesis of NHL. The antigen(s) involved in this process are unknown, although recent reports provide evidence that BCRs on lymphoma cells may recognize other malignant cells (stimulation in an autologous fashion) or antigens within the tumor microenvironment such as host stromal tissue or chronic infection with microbes.

Epidemiologic studies have bolstered the argument that chronic immune activation and inflammation are connected with NHL development; these data also suggest that immune surveillance also plays a role in the origin of NHL. DLBCL and Burkitt lymphoma (BL) occur more frequently in immunocompromised hosts and are often Epstein-Barr virus (EBV) positive. HIV/AIDS is a significant risk factor for post-GC neoplasms, and this risk is attenuated with the use of highly active antiretroviral therapy. For example, the risk of central nervous system lymphomas is increased more than 1000-fold in patients with AIDS. NHL also occurs more frequently in acquired or inherited immunodeficiencies such as common variable immunodeficiency and severe combined immunodeficiency and with solid organ and hemopoietic transplantation. Other clinical situations in which chronic infection or inflammation occurs have also been linked to NHL. Gastric MALT (*Helicobacter pylori*), hepatosplenic T-cell lymphoma (associated with infliximab use), and thyroid NHL (Hashimoto thyroiditis) are specific instances in which the development of lymphoid malignancy can be traced to chronic inflammation, either of microbial or autoimmune etiology. Finally, a critical association with EBV has been noted for posttransplant lymphoproliferative disorder, a disease that occurs in the setting of organ transplantation and immunosuppression targeting cellular immunity.

Beyond these factors, the contributions of other modifiable risk factors and heredity appear to play only a small role in NHL development. Several environmental factors (pesticides, Agent Orange,

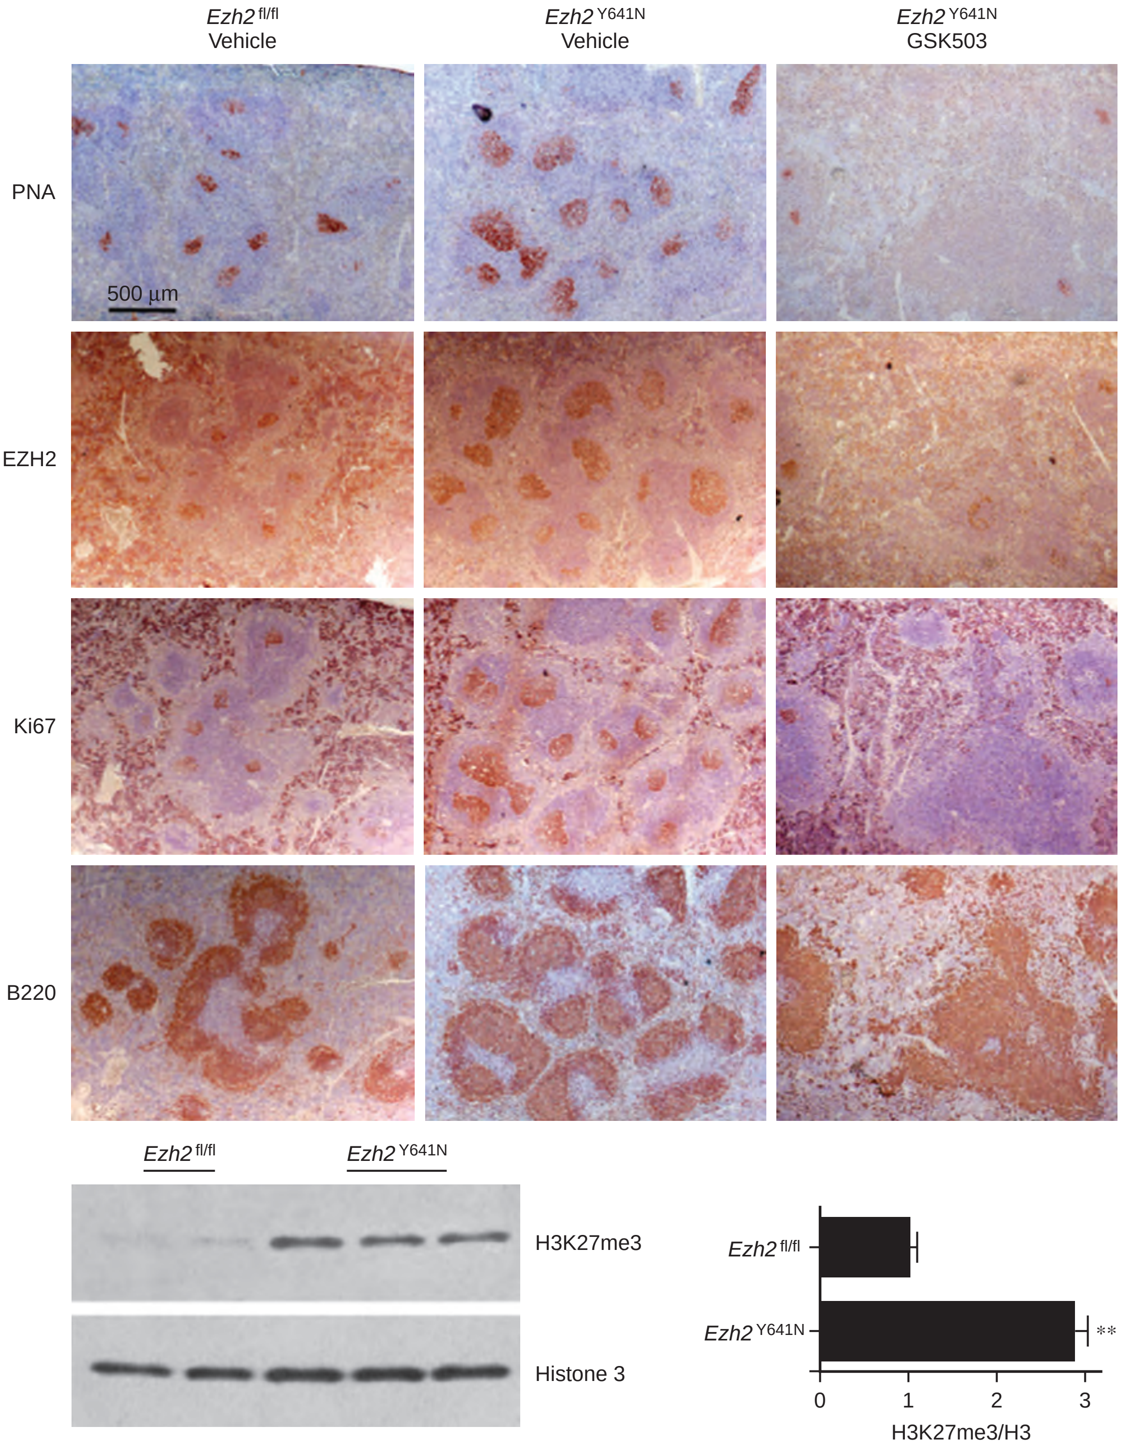

Figure 81.3 EXPANSION OF GERMINAL CENTERS WITH EZH2 MUTATION CONFERRING INCREASED HISTONE 3 LYSINE 36 TRIMETHYLATION (H3K36ME3). Upper color panels depict histologic staining as indicated by row (PNA, EZH2, Ki67, B220) of murine mouse model bearing wild-type versus mutant (Y641N) EZH2 with or without exposure to EZH2 inhibitor GSK503. Panels at bottom depict H3K36me3 levels according to EZH2 mutational status. *(From Béguelin W, Popovic R, Teater M, et al. EZH2 is required for germinal center formation and somatic EZH2 mutations promote lymphoid transformation. Cancer Cell. 2013;23(5):677–692.)*

radiation exposure) have been implicated in NHL, but the associations between these agents and lymphomagenesis are difficult to prove and the effect size of these factors appears to be relatively small. Pesticide exposure does appear to have a dose-effect relationship with regard to NHL pathogenesis and has been linked to recurrent t(14;18) cytogenetic rearrangements that are noted in DLBCL and FL, but the percentage of cases linked to pesticide exposure in these entities is very low. Likewise, several genetic linkage studies have found associations between several genes and the development of various lymphoma subtypes, but the role of variations in these pathways in lymphomagenesis has not been validated. Thus, there does appear to be a small role of inherited or modifiable risk factors that likely conspire with other acquired genetic/molecular lesions in the origin of lymphoma.

And so, factors related to abnormal immune surveillance, chronic inflammation, external exposures and host factors conspire to produce genetic/molecular lesions involved in lymphoma formation and progression. The remainder of this review will focus on current knowledge of biologic features of individual NHL subtypes.

DIFFUSE LARGE B-CELL LYMPHOMA

DLBCL is the most common subtype of NHL (≈25% of all NHL) and is responsible for more patient deaths than any other form of lymphoma. This entity often presents at an advanced stage, and around 50% of all patients fail to respond long-term to standard chemotherapy programs; the vast majority of those patients will eventually succumb to their disease. Even prior to the availability of GEP technology, it was clear clinically (based on tumor morphology, immunohistochemical staining, and patient outcomes) that DLBCL is a heterogeneous disease. Advances in molecular biology and genomic technologies have clarified the basis for some of this observed heterogeneity, and it has become clear that DLBCL comprises a diverse group of lymphomas that have distinct cellular origins, recurrent gene mutations, and chromosomal rearrangements that dictate their behavior. It is also clear that the stromal environment appears to play a key role in the development and progression of DLBCL, as with other cancers.

GENE EXPRESSION PROFILES DEFINE DIFFUSE LARGE B-CELL LYMPHOMA SUBTYPES (TABLE 81.1)

Histologic analysis and more recently high-throughput genomics assays such as GEP and massively parallel high-throughput sequencing for alterations (including somatic mutations, copy number changes, and gene fusions) have identified broad subtypes of DLBCL with molecular features that mimic their putative cell or origin; these studies have also shed light on the tremendous heterogeneity and complexity of the myriad features that drive lymphomagenesis.

GEP has identified GCB and activated B-cell–like (ABC) DLBCL subsets that express gene signatures that mimic GCs and activated B cells (Fig. 81.4). Roughly 30% of DLBCLs cannot be classified using this system and have been deemed unclassified DLBCL. There are thousands of genes that differ between these subtypes at the GEP level, which is a magnitude similar to that seen between acute myeloid and lymphoblastic leukemias, which have profoundly different mechanisms of origin and natural histories.

GCB DLBCLs express a characteristic spectrum of genes and have ongoing AID-mediated SHM as well as a histologic phenotype consistent with GC origin. BCL6 and LMO2 are both important to the transcriptional program of GCs and are commensurately overexpressed in GCB DLBCLs. Conversely, *PRDM1* is downregulated by BCL6, which results in decreased *PRDM1* activity in GCs, and GCB DLBCLs display a similar pattern. Histologically, GCB DLBCLs are characterized by CD10 expression and lack of IRF4 expression. Evaluation of Ig loci within GCB DLBCLs has also revealed evidence of ongoing SHM, which is further evidence that GCB DLBCLs reflect the biology of normal GC B cells and that dysregulation of pathways involved in GC formation might lead to this subset of DLBCL.

Alternatively, the ABC subtype of DLBCL expresses a post-GC phenotype but appears trapped just before differentiation into plasma cells. ABC DLBCLs are characterized by downregulation of many GC genes, including *BCL6* and *LMO2*, and by expression of genes associated with activated B cells and plasma cells. One of the hallmarks of the ABC DLBCL phenotype is upregulation of NFκB. NFκB is a transcription factor that targets a number of gene programs governing cell proliferation, immortality, and angiogenesis within NHLs. The effectors of NFκB signaling exist in inactive form in the cytosol and require signaling either through MAPK/ERK (mitogen-activated protein kinase/extracellular signal-regulated kinase) signaling (the canonical NFκB pathway) or through ligation of CD40–LTbR–BAFF-R (B-cell activating factor receptor), which results in phosphorylation of the inactive complex and translocation of either the p50–RelA or p52–Rel B complexes to the nucleus and subsequent transcription of target genes. In ABC DLBCL cell lines, a signaling complex involving CARD11, BCL10, and MALT1 (the CBM complex) constitutively activates NFκB signaling and selective knock-down of any of the components of this complex using RNAi or small molecule inhibitors and is lethal to ABC cell lines. Interestingly, a few GCB cell lines also demonstrate activation of NFκB and mutations in the NFκB pathway, which might confer sensitivity to inhibition of this pathway in those tumors. The mechanisms by which DLBCLs acquire and maintain constitutive NFκB activity are still being elucidated and may provide insights into the origin and into possible treatments for this entity.

TABLE 81.1 **Frequency of Recurrent Genetic Aberrations in Diffuse Large B-Cell Lymphoma Subtypes**

Genetic Feature	ABC DLBCL	GCB DLBCL	PMBL	Notes
BCL2 translocation t(14;18)	0%	40%–50%	20%	Alternatively translocated to light chain loci 5%–10% of time
BCL2 amplification	34%	10%	16%	
BCL6 translocation t(3;V)(q27;V)	25%	10%	20%	Variable translocation partners (14q32, 2p11, 22q11, 4p11, 6p21, 11q23)
3q amplification	25%	0%	<5%	
9q24 amplification	5%	0%	45%	
PRDM1/ *PRDM1* deletion/ mutation	25%	0%	Unknown	
REL amplification	0	15%	25%	
Recurrent mutation	*CARD11*, *MYD88*, *CD79B*	*EZH2*, *GNA13*, *BCL2*	*PTPN1*, *SOCS1*, *STAT6*	
MYC rearrangement t(8;14) (q24;q32)	5%–10% of all DLBCLs	25%–30% occur with t(14;18) (q32;q21)

Primary mediastinal B-cell lymphoma (PMBL) represents a distinct subset of patients that have sometimes been classified as

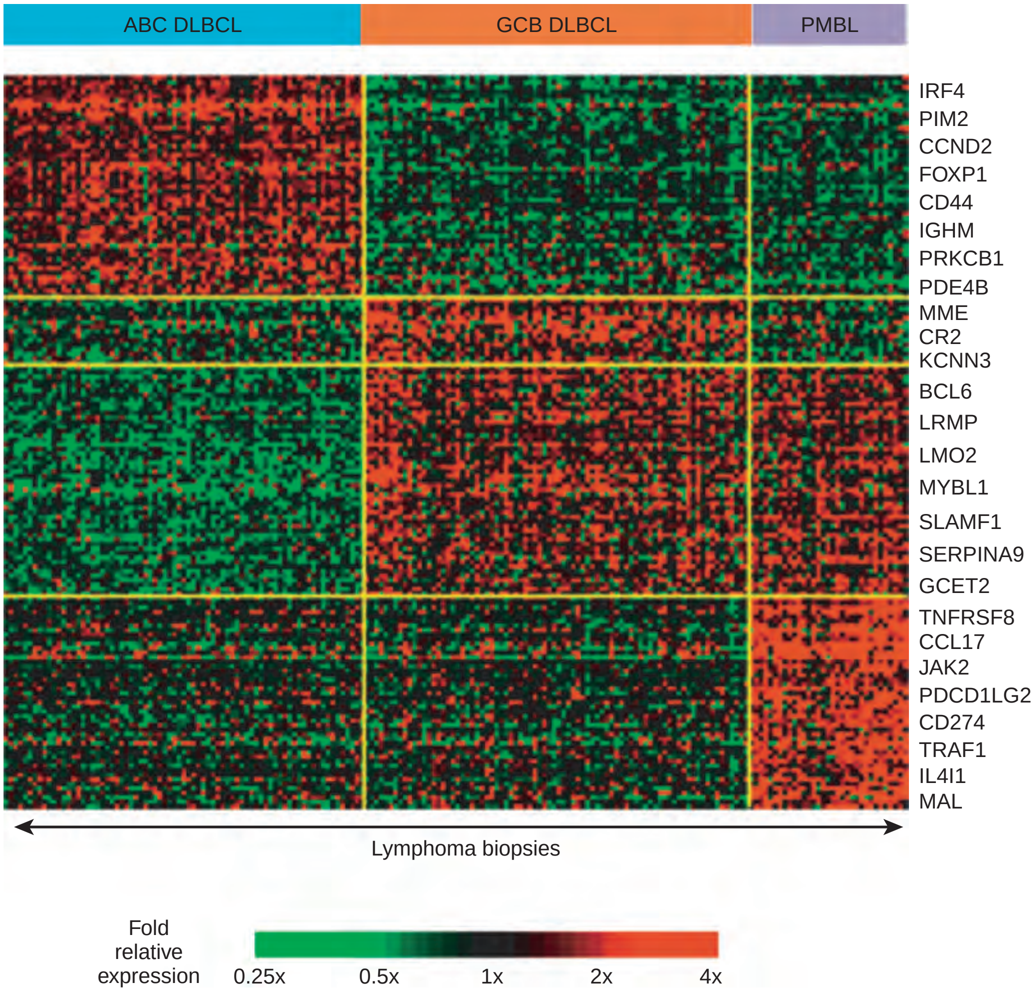

Figure 81.4 GENES CHARACTERISTICALLY EXPRESSED BY SUBGROUPS OF DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL). Activated B-cell–like (ABC) DLBCL, germinal center B-cell–like (GCB) DLBCL, and primary mediastinal B-cell lymphoma (PMBL). Each column represents gene expression data from a single DLBCL biopsy sample, and each row represents expression of a single gene. Relative gene expression is indicated according to the color scale shown. *(Adapted from Roschewski M, et al. Diffuse large B-cell lymphoma—treatment approaches in the molecular era. Nat Rev Clin Oncol. 2014;11:12-23.)*

DLBCL. PMBL was originally identified based on the clinical characteristics of the disease. Patients with PMBL are generally young (third or fourth decades of life), predominantly women, and present with a large mediastinal mass; outcomes with chemoimmunotherapy for PMBL are generally superior to those with other subtypes of DLBCL. GEP studies revealed that PMBL could be clearly delineated from ABC and GCB subtypes. Indeed, by gene expression, PMBL appears similar to Hodgkin lymphoma with many shared features in both diseases, including the expression of CD30 (Fig. 81.5). Both diseases also express genes associated with Janus-activated kinase (JAK)–signal transducer and activator of transcription (STAT) signaling as well as targets of the NFκB pathway.

Molecular Pathogenesis of Diffuse Large B-Cell Lymphoma

Investigation of the molecular landscape of DLBCL has revealed a set of recurrent cytogenetic and molecular abnormalities associated with pathogenesis. Chromosomal translocations involving *BCL6*, *BCL2*, and *MYC* (v-*myc* myelocytomatosis viral oncogene homolog) occur frequently in DLBCL, and these translocations appear to reflect cell-of-origin phenotype. 3q27 rearrangement with Ig gene partners is the most common rearrangement seen in DLBCL and occurs in about 30% of both the ABC and GCB subtypes. This genetic rearrangement upregulates the *BCL6* gene, resulting in an oncogenic phenotype. Additional mutations in the transcriptional regulatory program of *BCL6* may also occur with alternative translocation. Notably, *BCL6* translocations appear to not be sufficient for lymphoma formation as evidenced by mice bearing t(3;14) translocations that develop NHL at a low rate. *BCL2* translocations occur in a minority of GCB DLBCLs but are not seen in the ABC phenotype; this mirrors the situation in FL, in which *BCL2* overexpression results in disordered GC transit. *MYC* rearrangements additionally occur in DLBCL (≈5% of cases), sometimes with rearrangements of *BCL2, BCL6*, or both. These tumors, sometimes termed *double-hit lymphomas*, display an aggressive phenotype seemingly intermediate between BL and DLBCL.

Oncogenic mutations and areas of chromosomal amplification or deletion also appear important in the pathogenesis of DLBCL. Upregulation of c-REL occurs in about 20% of GCB tumors through amplification of the 2p locus. Amplification of *MYC* and *BCL2* may also occur through this mechanism. *TP53* mutations and SHM of other loci, including *PIM1, BCL6*, and *MYC*, also appear to contribute to lymphoma formation and progression. Mutations in *CARD11* causing constitutive NFκB activation have been described in a subset of both ABC and GCB DLBCLs and appear to drive oncogenesis in these tumors. Overall, the patterns of gene mutation and recurrent cytogenetic abnormalities add further complexity to the classification of DLBCLs.

Recurrent mutations of genes involved in DLBCL pathogenesis have also been reported. Most recently, several groups have reported

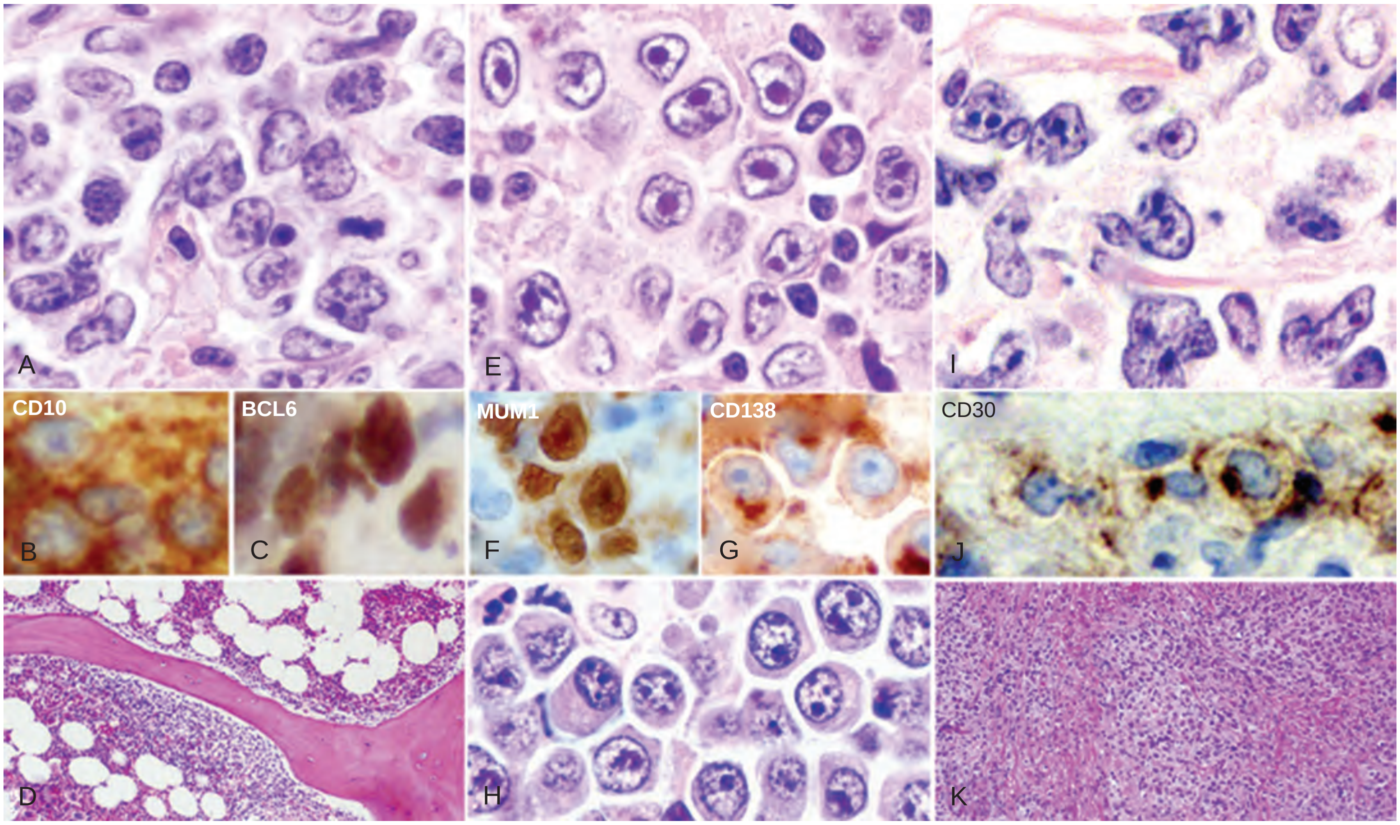

Figure 81.5 THREE TYPES OF DIFFUSE LARGE B-CELL LYMPHOMA DELINEATED BY HISTOLOGIC PATTERNS. Germinal center B-cell–like (GCB), activated B-cell–type, and primary mediastinal B-cell lymphoma (PMBCL) type. GCB, or germinal center (GC)–derived large B-cell lymphomas usually have a centroblastic morphology (A), are CD20$^+$, and express the GC markers CD10 (B) and BCL6 (C). In this case, the patient's staging bone marrow (D) showed paratrabecular involvement by small, cleaved cells (centrocytes), indicating that the large B-cell lymphoma likely arose from a lower-grade follicular lymphoma. Activated B-cell–like large B-cell lymphoma can sometime have an immunoblastic morphology (E) and can typically express MUM1 (F) and CD138 (G). These post-GC cell types of lymphomas can also have a plasmablastic morphology (H), as sometimes seen in HIV-related cases. PMBCLs are frequently composed of multilobated centroblasts (I). They are typically CD45$^+$, CD20$^+$, and usually CD30$^+$ (J) but CD15 negative. Surface immunoglobulin may be negative on such cases. PMBL is commonly associated with fibrosis, which is present in broad bands (K) or surrounding individual cells (as in I).

initial and now expanded/updated analyses of whole-genome, exome, or transcriptome data from the application of massively parallel sequencing in thousands of cases of DLBCL. DLBCL case clinical outcome data is now available in conjunction with recent data sets and allows for a refined analysis of features associated with treatment resistance and other clinical events in this entity (Fig. 81.6). These studies have identified hundreds of novel mutations in DLBCL and confirm previous descriptions of survival association with cell or origin and other phenotypic features. Two of these studies show DLBCL cases can be clustered into novel subgroups based on somatic alterations including SNVs, GEP, and CNVs, although these studies have somewhat different conclusions as to molecular grouping of DLBCL cases. It may be more appropriate to consider the contribution of various mutations with pathogenesis in a combinatorial factor as there is tremendous heterogeneity in the spectrum of mutations that participate. Interestingly, some of the molecular features of lymphoma subtypes such as activation of the NFκB signaling pathway identified through GEP have been shown to correlate with specific mutations in DLBCL cancer genes. Inactivating mutations of *PRDM1* and mutation in genes regulating NFκB signaling (*TNFAIP3, MYD88, CARD11*) have been noted in ABC DLBCL subtypes. *CD79B* and *BCL2* have also been found to harbor mutations in DLBCL and other NHLs. A series that performed RNA sequencing on 127 NHL samples (including 83 DLBCL tumors) found 651 coding single nucleotide variants (cSNVs), many of which were not previously documented in malignancies. Truncating deletions in tumor suppression genes (*TP53, TNFRSF14, CREBBP*) were among the most significantly mutated genes and other heavily mutated genes not previously known to be involved in DLBCL pathogenesis (including *MLL2, BTG1, EZH2*, and *GNA13*). *MLL2* contained cSNVs in 26% of tumors and most often occurred as a heterozygous defect, and sometimes multiple mutations occurred in trans fashion. MLL2 functions as a H3K4-specific methyltransferase responsible for regulation of transcription of developmental genes. Ostensibly, MLL2 might serve to deregulate genes involved in differentiation or development and act in conjunction with other oncogenes to facilitate NHL. Other groups have confirmed mutations in *MLL2* and other genes (*CREBBP/EP300*) that coordinate chromatin acetylation, leading to the hypothesis that mutations in histone-modifying genes lead to DLBCL and other NHLs. Further work is needed to dissect the mechanism(s) by which the various molecular lesions in individual tumors cause lymphoma formation and this will perhaps also improve our understanding of normal lymphocyte biology while providing new tools for lymphoma diagnosis and treatment.

The Tumor Microenvironment and Diffuse Large B-Cell Lymphoma

The complexities of antigen presentation and recognition and regulation of B-cell proliferation that occur in GCs suggest that the microenvironment may play a role in the origin and progression of DLBCL. Tumor-infiltrating T cells have been correlated to longer survival in patients with DLBCL, and failure of immune editing is likely responsible for the increase in NHL in HIV-positive and immunosuppressed persons. GEP has been used to define stromal elements related to DLBCL progression. In one series, hierarchical clustering was used to define three groups among DLBCL samples by GEP. Clusters identifying gene signature termed *oxidative phosphorylation,*

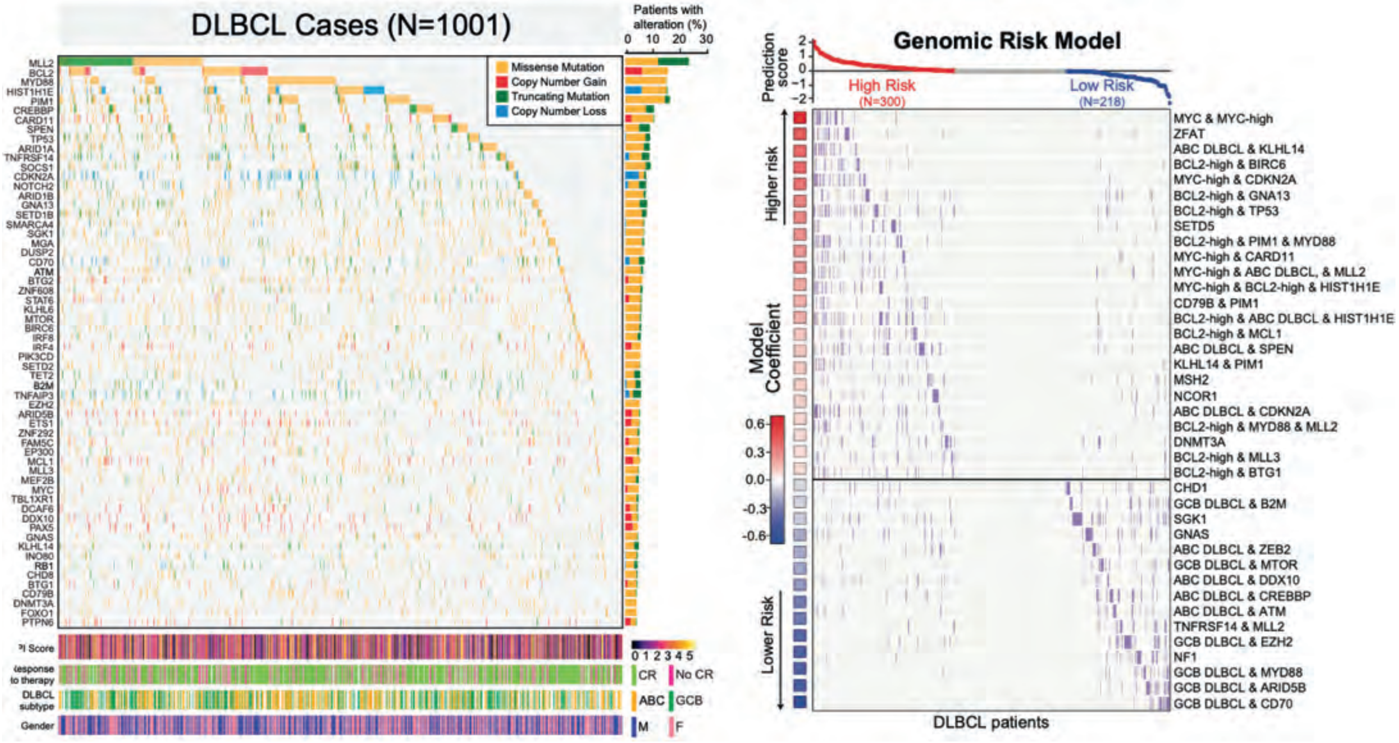

Figure 81.6 GENOMIC EVENTS IN DIFFUSE LARGE B CELL LYMPHOMA AND IMPACT OF MUTATIONS ON SURVIVAL WITH CHEMOIMMUNOTHERAPY. The left panel depicts the landscape of genetic mutations in diffuse large B-cell lymphoma (1001 cases) with clinical features such as International Prognostic Index (IPI) and chemotherapy response depicted for each case. The right panel depicts key molecular subgroups defined by collaborative mutation and gene expression profiling studies to identify key mediators of DLBCL pathogenesis and survival features. *(From Reddy A, Zhang J, Davis NS, et al: Genetic and functional drivers of diffuse large B cell lymphoma. Cell. 2017;171(2):481.–494.)*

BCR proliferation, and *host response* were identified; notably, the host response group exhibited gene expression profiles associated with T and natural killer cells, dendritic cells, and macrophages. This work illustrates that patterns of stromal involvement in DLBCL could play a key role in pathogenesis. In another series involving biopsy specimens from 414 patients treated with chemotherapy and chemoimmunotherapy, two gene signatures characterizing patterns of tumor stroma best predicted survival. Improved survival was noted with a pattern that included genes associated with the extracellular matrix and histiocytic infiltration. The converse was true for gene profiles correlating to angiogenesis because these were associated with far worse overall survival.

Although it is not known what roles distinct lymph node subsets play in the pathogenesis of lymphoma, it is clear from these studies that the tumor microenvironment plays a role in the origin of NHL.

Conclusions

DLBCL represents a heterogeneous group of B-cell neoplasms with a distinct underlying biology, prognosis, and response to therapy. Recent genomic approaches to studying DLBCL have identified a number of interesting potential targets for better prognostic stratification and treatment of this lymphoma entity. More work is needed to this end and to better understand the origin of DLBCL and the role of stromal factors in disease progression.

BURKITT LYMPHOMA

BL is a highly aggressive lymphoma entity characterized by a high mitotic rate, extranodal spread, and early death, but it is frequently curable with high-intensity multi-agent chemotherapy. It was first described more than 50 years ago as a disease in young Africans in association with EBV infection. Since then, the sporadic and immunodeficiency-related forms of the disease have been described. Subsequent work has shown that translocation of the *MYC* gene on chromosome 8q24 to the Ig locus occurs in virtually all cases of BL (Fig. 81.7). Given the high prevalence of *MYC* rearrangements and the high cure rates observed with chemotherapy, many have studied BL as a model for other B-cell lymphomas.

Overexpression of MYC occurs in association with a GC phenotype in BL. BL tumors typically display the immunophenotypic characteristics of GC B cells, and genetic and genomic studies have reinforced this notion of GC origin. In virtually all cases, rearrangements are found between the MYC locus and one of the Ig genes, most commonly with the IgH locus at 14q32.33 in more than 80% of cases. Alternative rearrangements involving MYC and the κ or λ light chain regions are also noted in a minority of cases. Two different patterns of rearrangement and SHM have been noted among the three types of BL. In endemic BL, chromosome 14 breakpoints can be mapped to J_H regions, indicating *RAG1*- or *RAG2*-mediated rearrangement occurring at the pro–B cell stage. In contrast, sporadic and immunodeficiency-related BL often demonstrate SHM and rearrangement at chromosome 14 breakpoints related in Ig switch regions; this is consistent with GC or memory B-cell origin.

Translocations placing MYC downstream of Ig genes result in massive gene upregulation and oncogenesis by dysregulation of multiple pathways. In normal B cells, MYC regulates B-cell proliferation and differentiation and is tightly regulated by multiple mechanisms, including posttranslational modifications and transcriptional autoregulation and by other factors, including a careful balance of interactions with regulatory proteins. Under normal circumstances, MYC also induces a number of proapoptotic cellular mechanisms, which are then perturbed when MYC is overexpressed by the robust Ig gene promoters existing in GC B cells. Constitutive induction of MYC expression in GCs via the upstream Ig gene promoter then confers a neoplastic phenotype. Highlighting the complexities of MYC in this setting, even brief reversal of MYC overexpression may induce a

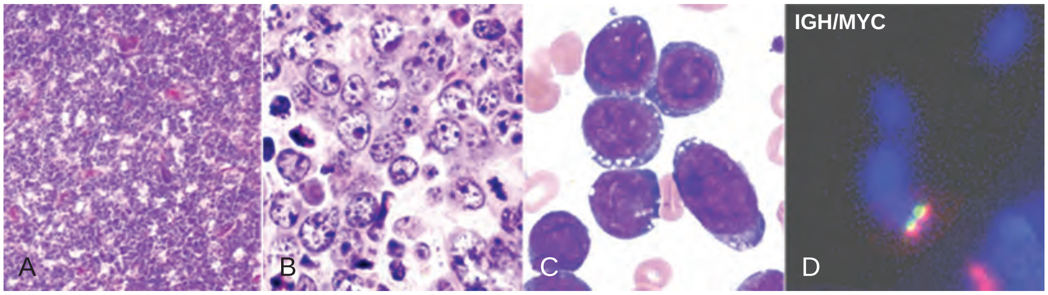

Figure 81.7 BURKITT LYMPHOMA (BL). (A) A case of BL illustrated at low power showing the "starry sky" appearance. This appearance is attributable to the dense proliferating cells producing the "dark sky," and the scattered lighter staining tingible body macrophages ("stars") phagocytizing dying cells. (B) Higher magnification image illustrating the syncytia of intermediate-sized cells with coarse chromatin and multiple nucleoli. Note the tingible body macrophage with abundant light cytoplasm and ingested debris *(center bottom)*. (C) Burkitt cells as seen on a Wright-stained bone marrow aspirate in a patient with BL. Notice deep blue cytoplasm with numerous vacuoles. (D) Fluorescence in situ hybridization with probes to MYC and immunoglobulin h (IgH) illustrate the IgH–MYC fusion. *(Courtesy Dr. Yanming Zhang, University of Chicago.)*

reversion of tumors to a benign phenotype; this implies that c-*MYC*–Ig rearrangements might serve as the "switch" that drives BL formation in the context of GCs.

Recently, GEP has further examined the role of MYC in BL and revealed insights into the similarities and differences between BL and other GCB-origin NHLs (Fig. 81.8). This work has further defined the differences between BL and DLBCLs carrying MYC rearrangements because these entities can be difficult to distinguish on histopathologic grounds alone. Although BL is characterized by gene expression profiles consistent with GC origin, a group of genes found in GCB DLBCL, including *LMO2, BCL2, CD80*, and *CD86*, are expressed only weakly in BL. BLs also express low amounts of NFκB and major histocompatibility class I molecules compared with DLBCL. These data also serve to allow the diagnostic distinction of BLs on molecular grounds. In two large studies, a fraction of DLBCLs were classified as BL in instances when there was DLBCL–BL overlap, causing disagreement among pathologists. The outcome with CHOP-like chemotherapy in these instances was associated with poorer survival. Furthermore, classic MYC t(8;14) rearrangements and intermediate molecular phenotypes were also associated with worse overall survival.

The development of a molecular diagnosis for BL aids in distinguishing BL from DLBCL and further illustrates the complexity of *MYC* rearrangements in NHL. Lymphoma entities containing MYC rearrangement in addition to rearrangements in *BCL2* or *BCL6* have been historically termed "double-hit" lymphomas. This subtype frequently has a clinical behavior distant from BL and is often associated with progressive disease, a high International Prognostic Index score, and poor response to intensive chemotherapy regimens. More work regarding this subtype of NHL is needed to understand its pathogenesis.

Aside from gene expression patterns related to GC origin, further genomic alterations may contribute to BL pathogenesis. As in DLBCL, whole genome/exome/transcriptome approaches have deepened our understanding of the importance of genetic lesions beyond *MYC* rearrangement in BL pathogenesis (Fig. 81.9). While *MYC* mutation (occurring in addition to *MYC* rearrangement) appears to be the most frequent mutation in BL, mutations in the transcription factor *TCF3* or its negative regulator *ID3* occur in the majority of cases of BL and appear to lead to phosphoinositol-3-kinase activation and other complex transcriptional changes with BL cells. *ID3* mutations may also serve as a regulator of *MYC* and directly influence cell cycle progression, thus fostering BL development. TP53 is frequently also mutated or deleted in a subset of BL tumors. High-throughput genomic techniques have revealed many other novel BL cancer mutations in genes such as *SMARCA2* and *CCND3* and recurrent copy number abnormalities including gains of 1q and 18q and deletion of 19p13. Thus these studies have revealed molecular complexity beyond the dysregulation of *MYC* through cytogenetic rearrangement.

EBV infection is also thought to play a role in the development of BL because virtually 100% of cases of endemic BL and 30% to 50% of all other BLs are associated with EBV positivity. The exact role of EBV in BL is unclear. Endemic BL is frequently associated with endemic malaria, which further suggests a complex interaction of the host immune response with microorganisms and other factors. Interestingly, *Plasmodium infection* appears to promote genomic instability and promote AID-dependent B-cell lymphomas and this mechanistically supports a link between chronic infection and resultant immune stimulation or dysregulation and lymphoma formation. Other host factors or genomic changes may further contribute to the development of BL.

Further work is needed to define what other genomic changes and host–environmental interactions contribute to the pathogenesis of BL. Ongoing studies seeking to define the entire spectrum of molecular, immunologic, genomic, and epigenetic changes associated with BL pathogenesis may further elucidate this process.

FOLLICULAR LYMPHOMA

FL is a low-grade B-cell neoplasm that is also characterized by recurrent chromosomal rearrangements involving the IgH locus. It is the most common indolent NHL with more than 16,000 adults diagnosed yearly in the United States. It is characterized by significant heterogeneity with regard to histologic grade and overall survival, with more than 10% of patients surviving at least 15 years after diagnosis. A spectrum of histologic grading based on the density of centroblasts is also characteristic of this disorder, with higher FL grades resembling DLBCL. There is no clear association between grade and clinical outcome in the disease. Some patients with FL experience an aggressive clinical course and transformation to aggressive lymphomas, but others may experience disease progression only after many years with the disease. This review focuses on the classic rearrangements of *BCL2* and the additional molecular changes associated with FL development and with histologic transformation of FL to more aggressive subtypes.

BCL2 Rearrangements and Other Genomic Alterations in Follicular Lymphoma

FL arises from GC B cells that have been immortalized at this stage of B-cell differentiation. Cytogenetic studies performed in the early 1970s defined a recurrent translocation involving the long arms of chromosomes 14 and 18 in more than 90% of FL cases. Further investigation revealed that this places the gene encoding the important antiapoptotic gene *BCL2* downstream of the Ig heavy chain transcriptional regulators. The BCL2 protein inhibits the release of cytochrome c from mitochondria in the process of apoptosis. In normal GCs, *BCL2* is essentially absent because selection of B-cell clones via apoptosis is an important step in the production of high-affinity Ig idiotypes. The t(14;18)(q32.3;q21.3) appears to

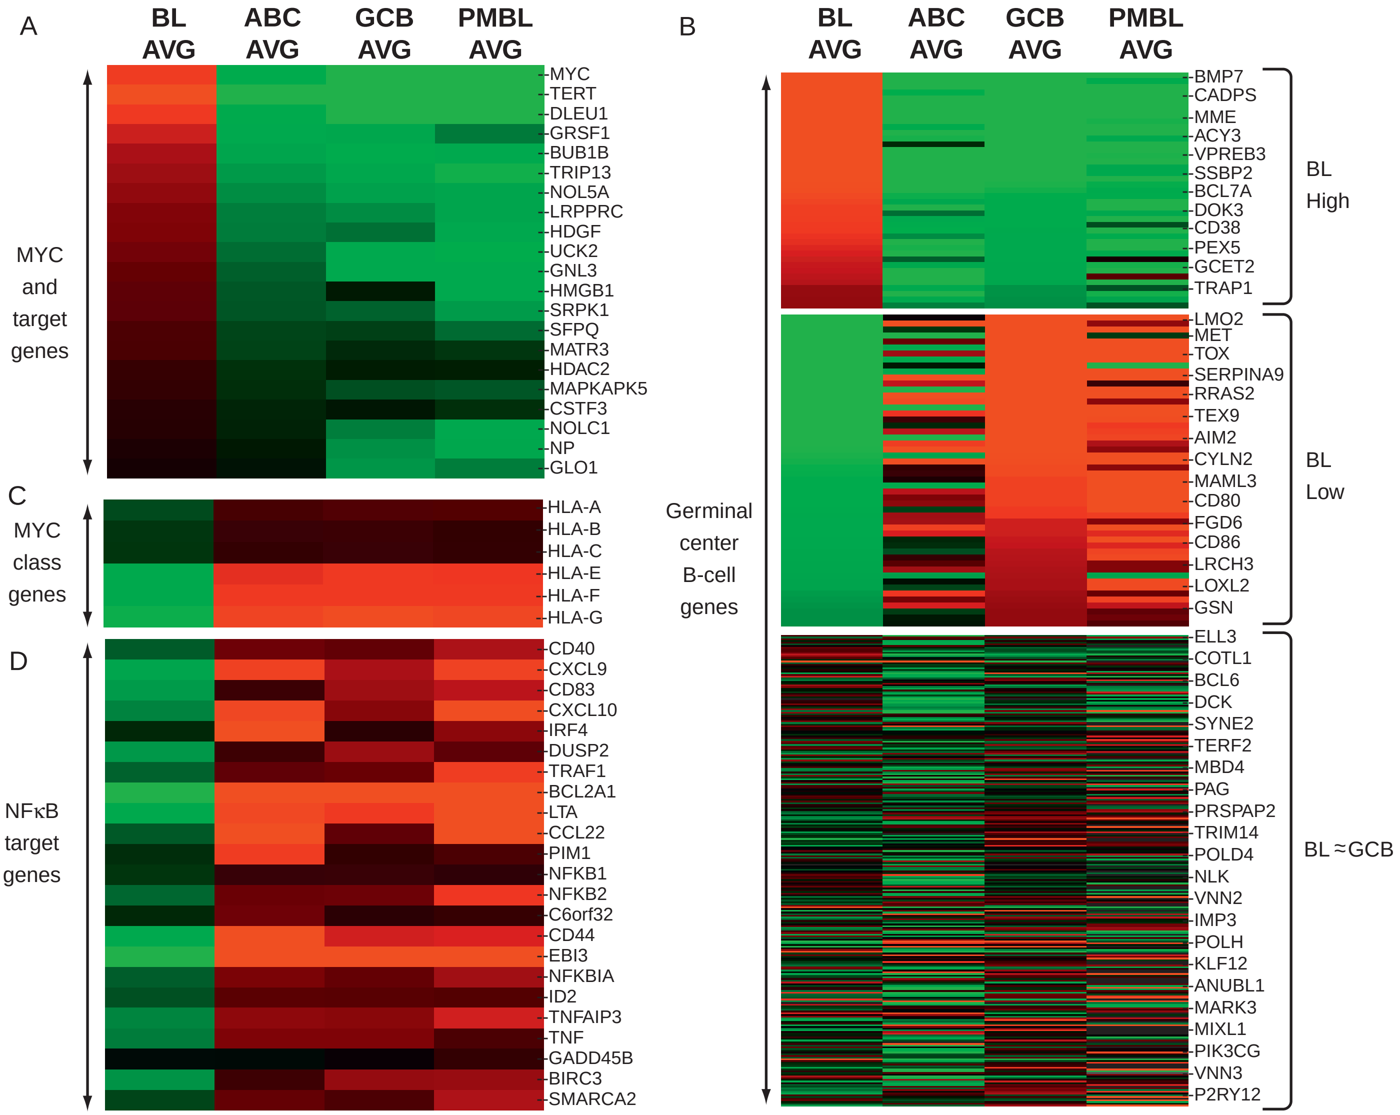

Figure 81.8 GENE EXPRESSION PROFILES IN BURKITT LYMPHOMA (BL) COMPARED TO DLBCL Relative expression of genes that distinguish BL from subgroups of diffuse large B-cell lymphoma (DLBCL)—activated B-cell–like (ABC) DLBCL, germinal center B (GCB) DLBCL, and primary mediastinal B-cell lymphoma (PMBL)—is categorized into gene expression signatures: c-myc and its target genes (A); genes that are expressed in normal germinal center (GC) B cells (B) and are expressed more highly (BL-high), less highly (BL-low), or equivalently (BL≈GCB) in BL than in GCB DLBCL; major histocompatibility class I genes (C); and genes targeted by the nuclear factor kappa-B (NFκB) signaling pathway (D). GC B-cell signature genes are those that were overexpressed in normal GC B cells, compared with blood B cells. The "BL-high" genes were expressed at levels twice as high in BL as in GCB DLBCL ($P < .001$). The "BL-low" genes were expressed at levels twice as high in GCB DLBCL as in BL ($P < .001$). The expression levels of the "BL≈GCB" genes did not differ significantly between the two lymphoma subtypes. *(Reproduced from Dave SS, Fu K, Wright GW, et al. Molecular diagnosis of Burkitt's lymphoma. N Engl J Med. 2006;354:2431.)*

be mediated by *RAG1/RAG2* in pre-GC B cells because *BCL2* is most often found juxtaposed to J chain exons. Isolated t(14;18) is not sufficient to induce FL because transgenic mice bearing this translocation develop lymphoid hyperplasia but require other genetic lesions to develop FL. Additionally, B cells with t(14;18) can be isolated from apparently normal individuals who never develop lymphoma, and *in situ* follicular hyperplasia with BCL2 overexpression has been noted on examination of otherwise normal lymph nodes. This suggests that other lesions must be acquired for development of FL; a preponderance of evidence suggests this occurs in GCs. Histologically, FL is characterized by an abnormal follicular architecture containing neoplastic cells. The follicles loosely resemble GCs but usually lack an appreciable mantle zone but generally occur in close proximity to follicular T-helper cells expressing CD3, CD4, CD57, PD1, and CXCL13. FL usually exhibits a CD10+BCL6+IRF8+ GC-like phenotype in association with ongoing SHM, confirming GC or post-GC origin (see Fig. 81.8). One obvious hypothesis is that BCL2 overexpression dysregulates apoptosis such that GC transition and SHM result in further genomic and epigenomic changes that result in FL. This framework might need to be reexamined in the small proportion of FL cases that do not express BCL2.

Although BCL2 is thought to have a critical role in development of FL, nearly 30% of grade 3A and a majority of grade 3B FLs are t(14;18) negative. Alternative rearrangements involving the κ or λ light chains and *BCL2* may occur, but many t(14;18) FLs do not express BCL2. These entities express a post-GC CD10-IRF4-phenotype with 3q27/*BCL6* rearrangements and are associated with lower chemotherapy response rates as well as worse overall survival compared with t(14;18)-positive FLs. It is not clear how this subset of FL evolves from normal B cells, but this immunophenotype suggests a late- or post-GC origin. GEP and analysis of miRNA profiles of FL confirm this association. Leich et al. analyzed gene expression profiles of 184 grade I-3A FLs, of which 17 were t(14;18) negative (six of these rearrangement-negative FLs still overexpressed BCL2). Analysis of this data showed enrichment of signatures associated with

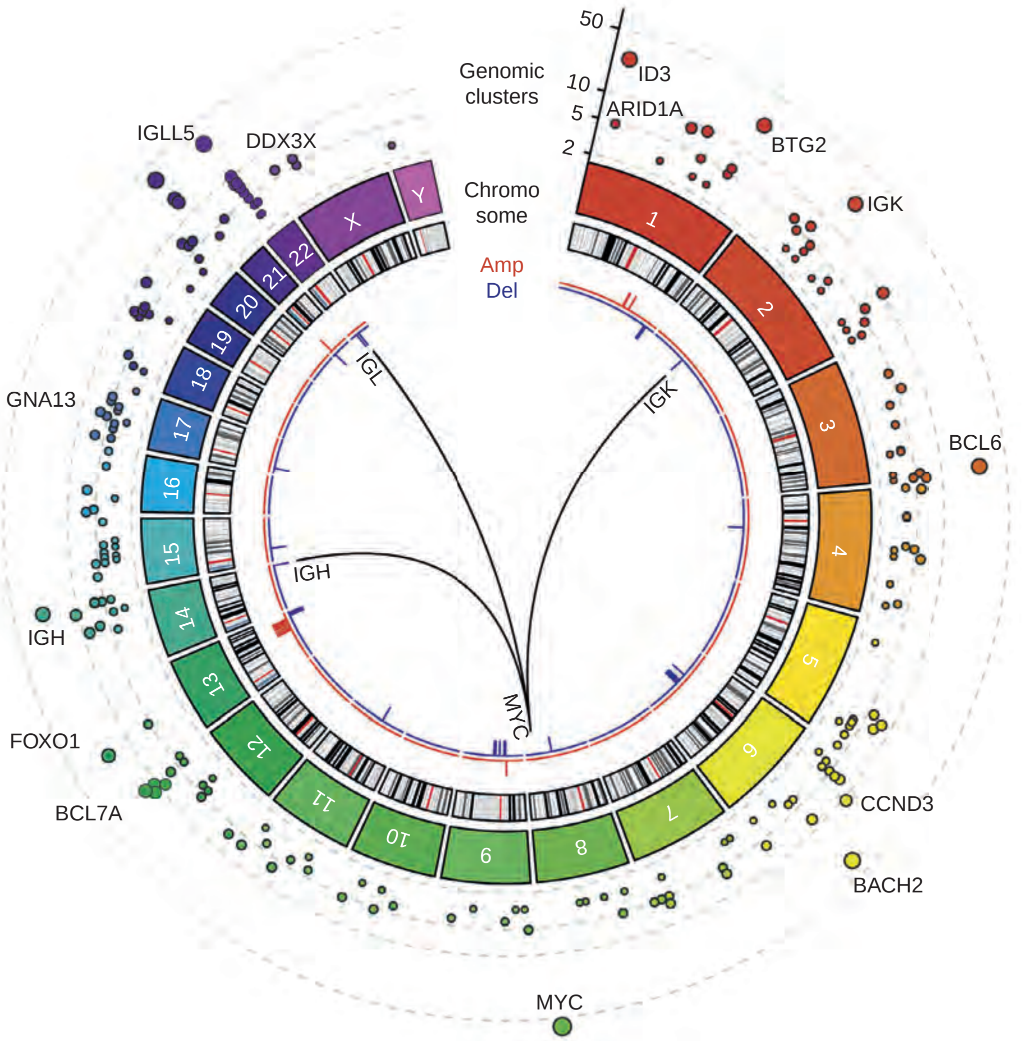

Figure 81.9 COMMON SOMATIC ALTERATIONS ACROSS THE ENTIRE BURKITT LYMPHOMA (BL) GENOME. CIRCOS diagram shows whole genome landscape of BL in regard to SNVs, gene amplifications and deletions, and gene fusions. Outer rings depict most common SNVs at gene level stratified by rate of mutation found in BL cases and chromosome coordinate locations are denoted by color/number. Inner ring and links show most common gene fusions including *MYC* and *IG* partners. *(Reproduced from Panea RI, et al. The whole-genome of Burkitt lymphoma. Blood. 2019;134(19):1598–1607.)*

activated B cells, including NFκB signaling, and those associated with cell cycle, proliferation, and the tumor microenvironment. A study involving a similar cohort showed that a pattern of 17 miRNAs was differentially expressed between translocation positive and negative phenotypes. A group of five miRNAs was found to be downregulated in the t(14;18) group, and this correlated to overexpression of genes related to proliferation, apoptosis, and differentiation. Thus evidence for a post-GCB origin of t(14;18) translocation–negative FLs exists at the gene expression level. Further work is needed to fully understand how BCL2-negative FL develops.

Similar work with BCL2-positive FL has revealed the additional steps required for FL development after t(14;18). Conventional cytogenetic studies in FL reveal recurrent duplications of 1p36 and 6q and gains of chromosomes 2, 8, 17, 21, and X. Additionally, SHM appears to affect glycosylation status of surface Ig, implicating BCR signaling in FL pathogenesis. As in DLBCL, FL is characterized by frequent mutations in genes involved in epigenetic regulation of gene expression including ARID1A, MLL3, and CREBBP as well as other genes involved in cellular proliferation and avoidance of apoptosis such as *TP53*, *MCL1*, and *TNFRSF14*.

Further genomic changes and host factors have also been delineated for DLBCL arising from FL. Histologic transformation is associated with further mutations or deletions in *TP53* and *p16* and appears to occur by distinct mechanisms involving either clonal evolution or by transformation of a putative progenitor FL stem cell. Acquired rearrangement of the MYC oncogene can also occur and has been associated with an aggressive plasmablastic phenotype. Stromal factors with FL tumors also likely play a key role in FL propagation and have been studied as having prognostic consequence in FL as well.

Tumor Microenvironment and Survival in Follicular Lymphoma

Just as the lymphoid microenvironment is integral to the formation and function of GCs and immune factors predict survival in DLBCL, FL development appears to depend on stromal factors and the host immune response. In the largest study examining this relationship Dave et al. performed gene expression analysis using whole-genome microarrays on 191 FL specimens with the goal of determining genomic predictors of survival. Genes identified were stratified into two groups based on correlation of expression with patient outcome (gene sets associated with good prognosis or poor prognosis). Hierarchical clustering then identified five survival gene sets within each of these groups; analysis revealed that a combination of two gene sets (immune response-1 and immune response-2) formed the best model for prediction of survival. Interestingly, immune response-1

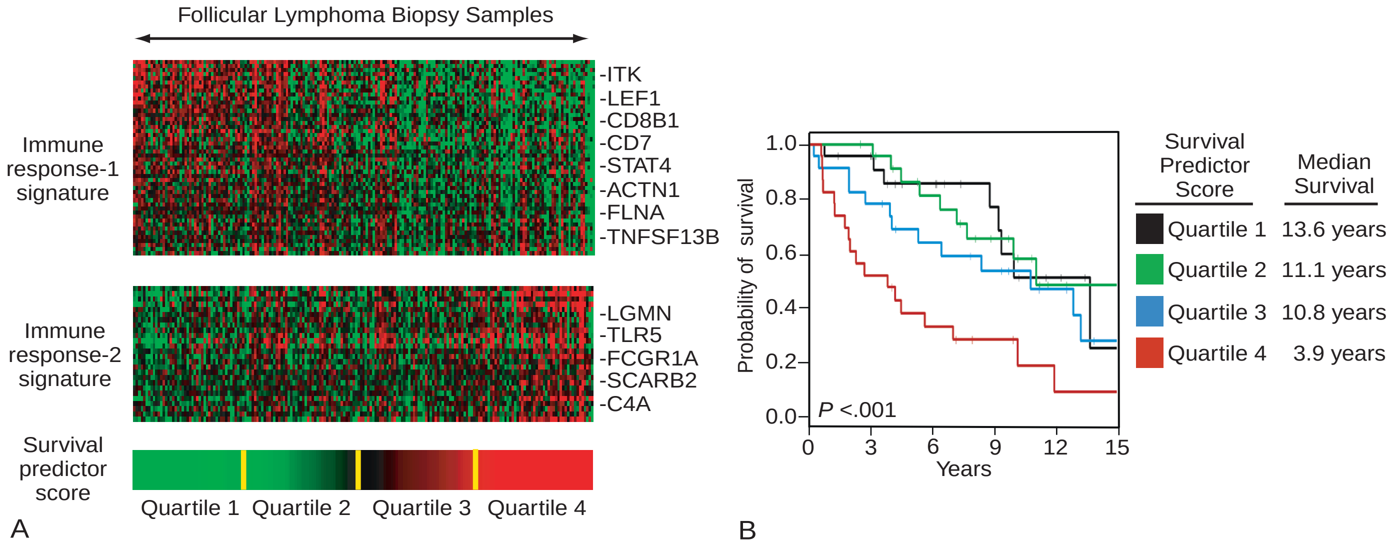

Figure 81.10 SURVIVAL IN FOLLICULAR LYMPHOMA (FL) CAN BE PREDICTED USING FEATURES OF THE TUMOR MICROENVIRONMENT. (A) Two sets of coordinately expressed genes, termed the *immune response-1* and *immune response-2 signatures*, are associated with survival in FL. The expression pattern of each gene in these two signatures is shown for FL biopsy samples. Expression of the immune response-1 signature is associated with favorable survival after diagnosis, and expression of the immune response-2 SIGNATURE is associated with adverse survival. These signatures are combined into a multivariate model of survival that generates a survival predictor score for each patient. Patients are ranked according to this survival predictor and divided into four equal quartiles as shown. (B) Kaplan-Meier plot of overall survival of patients in the four quartiles of the survival predictor. *(A, From Dave SS, Wright G, Tan B, et al. Prediction of survival in follicular lymphoma based on molecular features of tumor-infiltrating immune cells. N Engl J Med. 2004;351:2159.)*

consists of genes (*CD7, CD8B1, ITK, LEF1, STAT4*) associated with specific T-cell populations and macrophages. Conversely, immune response-2 consisted of genes found in dendritic cells and macrophages and was devoid of genes expressed by T-cell subsets (Fig. 81.10). Comparison with T-cell genes suggested a complex relationship with immune response-1 rather than a simple preponderance of T cells in the tumor biopsy.

Several hypotheses can be generated regarding the implication of these findings in FL biology. Given the relationship of genes involved in the immune response to survival, a direct impact of T-cell effector subsets in FL tumors could be one conclusion. Conversely, poor-risk tumors may be those that have become independent of FL follicles and therefore are more aggressive; this may be reflected in the variability of the immune response gene signatures seen across FLs. The impact of immune factors has been seen in other studies as well because survival may depend on FoxP3+ regulatory T-cell subsets, infiltration of macrophages, and the peripheral total monocyte count. Further work is needed to more clearly identify how the FL microenvironment impacts FL development and progression and to clarify whether manipulation of the immune compartment may be used therapeutically.

MANTLE CELL LYMPHOMA

Mantle cell lymphoma (MCL) is characterized by the chromosomal translocation t(11;14)q13;q32, which places cyclin D1 under the transcriptional control of the IgH promoter. MCL is predominantly a disease of elderly men and is characterized by a rather short median survival of 5 to 7 years. Histologic evaluation divides MCL into classic and blastoid variants, with the blastoid subtype having worse survival. Subgroups can also be defined on the basis of somatic mutations in the IgH loci because Ig-mutated tumors tend to have a more indolent disease as is the case with chronic lymphocytic leukemia (CLL), another CD5$^+$ neoplasm. This suggests two disparate origins for MCL with one subtype arising from pre-GC B lymphocytes and another stemming from cells that have encountered antigen and consequently have undergone SHM. Genomic approaches have also identified molecular profiles delineating MCL from histologically similar neoplasms and identified factors associated with survival. Notably, a minority of patients with MCL are cyclin D1-negative, and GEP has been useful in identifying this entity; further work in this area has identified numerous genomic lesions and molecular pathways involved in MCL. Herein the pathogenesis of MCL is reviewed focusing on the genomic and molecular basis of this disease.

Cyclin D1 and Mantle Cell Lymphoma

The genetic hallmark of MCL, the t(11;14) (q13; q32) translocation, juxtaposes the *CCND1* gene to the IgH locus, leading to overexpression of the cell cycle regulator cyclin D1. The three D-type cyclins (D1, D2, and D3) play an important role in cellular proliferation by propelling cells from G_1 to S phase of the cell cycle. Each forms heterodimers with the cyclin-dependent kinases CDK4 and CDK6, thus forming active kinase complexes. These complexes inactivate retinoblastoma protein (Rb) and bind to p27kip1, which functions to facilitate cell entry into the S phase of the cell cycle and consequent proliferation.

Cyclin D1 is not expressed in normal lymphocytes, and t(11;14) thus represents a pathogenic event in the origin of MCL. The gene encoding cyclin D1 *(CCND1)* consists of five exons that are alternatively spliced into two isoforms, cyclin D1a and D1b. Cyclin D1b does not appear to play a role in MCL. The proliferative capacity of MCL tumors appears closely tied to the degree of cyclin D1a overexpression. MCLs carry mutations in the 3′ untranslated region of *CCND1* that serve to stabilize cyclinD1a transcripts by removing miRNA (miR15/16) binding sites and deleting mRNA destabilizing elements. These sequences usually result in cyclin D1a being an unstable entity, with a half-life of less than 1 hour, but in MCL, these deletions or mutations result in cyclin D1a accumulation and increased cellular proliferation. Additional mutations in the translated regions of cyclinD1 result in protein stabilization through the blockade of GSK3β-mediated nuclear export of cyclin D1.

A minority of patients with MCL are cyclin D1 negative and are alternatively characterized by overexpression of cyclin D2 or D3. These derangements serve to deregulate the G_1–S transition in a manner similar to t(11;14) and highlight the theme that MCL is a disease created by cyclin complex–mediated cell cycle progression aided by upregulation of several molecular pathways associated with cellular proliferation and genomic instability.

Secondary Genomic Alterations in Mantle Cell Lymphoma

Beyond t(11;14), MCL is characterized by extensive genomic instability relative to other NHLs, and a variety of genetic lesions appears to drive proliferation of these tumors. Recurrent chromosomal losses, gains, and amplifications are seen in MCL, and many of these affect a large proportion of cases. Secondary genetic instability may occur as a result of aberrant DNA replication in the setting of deregulated S phase transition mediated by cyclinD1–CD4^{-}complexes. Acquired lesions in genes mediating cellular response to DNA damage and microtubule dynamics may contribute to the accumulation of these alterations as well.

Many (30% to 50%) of MCL cases are characterized by mutations or deletions in the DNA damage response pathway mediated by ATM and TP53 or modifiers of this pathway such as MDM2 and p14/ARF. *ATM* is often mutated with loss of the other chromosomal alleles. TP53 may also be downregulated in these tumors via similar mechanisms, and overexpression of TP53-negative regulators MDM2 and MDM4 also occurs via copy number amplification (examples of MCL histology with cyclin D1 and p53 staining are shown in Fig. 81.11). These overall serve to deregulate important cellular machinery involved in DNA damage repair, apoptosis, and cell cycle arrest, leading to increased cell cycle progression and proliferation in MCL. Further deletions at 9p21 occur frequently in MCL and serve to enhance cell cycle progression and block apoptosis. The 9p21 locus encodes p16(INK4a) and p14(ARF), which function as tumor suppressors. p16(INK4a) inhibits CDK 4/6 complex binding to cyclin D1, which results in decreased cell cycle progression. Deletion of p16(INK4a) in the setting of t(11;14) enhances proliferation in MCL and has been associated with worse overall survival. The function of p14(ARF) in MCL pathogenesis is less clear, but p14(ARF) blocks MDM2-mediated TP53 ubiquitination; p14(ARF) has other effects on cellular proliferation that usually work in a homeostatic pattern. Interestingly, cyclin D1 levels and INK4a/ARF deletions both correlate to a MCL proliferation signature created using GEP. Using a similar strategy, cyclin D1 expression levels and the presence of INK4a/ARF deletion have been used to create a predictor of overall survival using a cohort of MCL patients. Survival among groups stratified by this approach varies widely (from 6 to 7 years to <10 months), which confirms the importance of involvement of genes involved with the cell cycle and proliferation in MCL. This parallels the experience noted with histologic markers of tumor proliferation because Ki-67 (a marker of actively dividing cells) and the presence of blastoid features have previously been shown to correlate with worse outcomes.

When considered together, the recurrent deletions and mutations noted in MCL illustrate the importance of unchecked cell cycle progression in this disorder. DNA instability is another hallmark of MCL that appears to result from the blockade of cell cycle checkpoints in the setting of ongoing DNA damage. These factors are intertwined in a complicated fashion in MCL and further work to upregulate several diverse molecular pathways involved in cellular proliferation and survival.

Molecular Pathways and Profiles in Mantle Cell Lymphoma

A variety of molecular pathways have recently been described as being active in MCL. These include signaling pathways facilitating cellular proliferation, avoidance of apoptosis, evasion of immune editing, and cellular microenvironment interactions. As in other NHLs, GEP has been used to define a molecular diagnosis of MCL and identify genes and molecular pathways involved in its pathogenesis.

Genomic approaches identify a subset of MCL that is cyclin D1 negative and has features similar to other CD5+ B-cell neoplasms such as CLL. Although such cases are indistinguishable by histologic analysis, GEP demonstrates that these tumors express gene signatures that are otherwise nearly identical to cyclin D1+ MCL but lack the classic t(11;14) rearrangement. Overexpression of other D cyclins (cyclin D2 or D3) via rearrangement, amplification, or other mechanisms is found in many of these cases; this is consistent with the underlying theme that MCL is a disease of disordered cell cycle progression. Using a similar approach, *SOX11* has been identified as a sensitive and specific marker of MCL regardless of cyclinD1 expression status. *SOX11* encodes an HMG-box transcription factor that regulates embryogenesis and is important in neural development. Because greater than 90% of MCL specimens overexpress *SOX11* and this finding is rare in histologically similar NHLs, *SOX11* is a potentially useful marker for improving the diagnosis of MCL. *SOX11* has also been incorporated into prognostic models of MCL using histologic, clinical, and GEP data. Reports regarding the clinical significance of *SOX11* have been conflicting. Thus further work is needed to understand the molecular mechanisms underlying *SOX11* expression in MCL and the implications in this disease.

MCL has also been characterized by expression of several molecular pathways that enhance cellular proliferation and metabolism and are tightly intertwined with abnormalities in cell cycle regulation

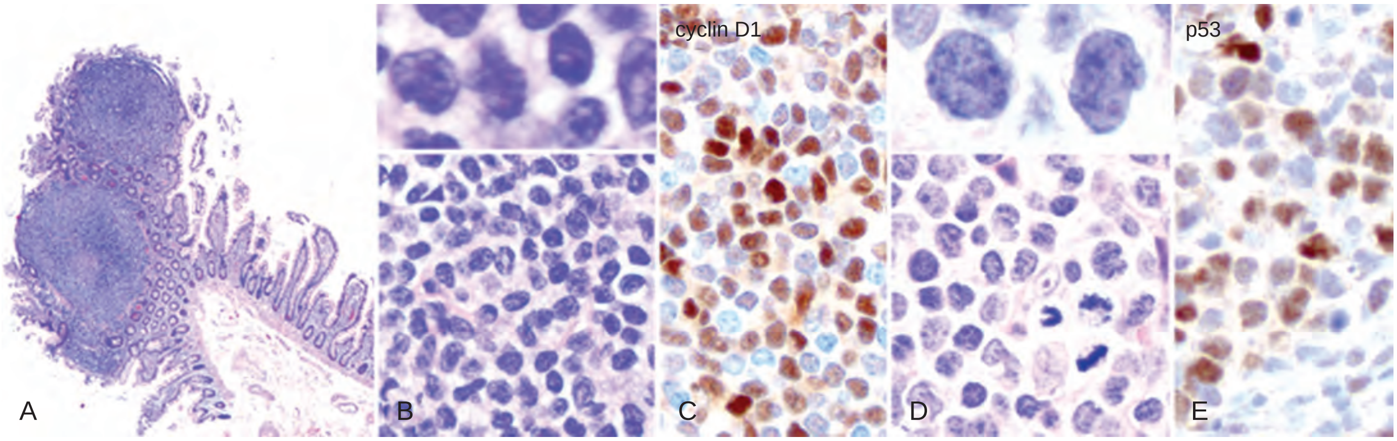

Figure 81.11 MANTLE CELL LYMPHOMA (MCL). (A) A case of MCL presenting as lymphomatoid polyposis. (B) The lymphoma cells are small to intermediate in size and have irregular nuclear contours and condensed nuclear chromatin. The cells were CD19^{+}, monoclonal B cells with λ light chain restriction, coexpression of CD5, FMC-7, and lack of CD23. (C) The cells showed cyclin D1 expression by immunohistochemical staining. The t(11;14)(q13;q32) was detected by conventional cytogenetic analysis. (D) In comparison, the blastoid variant of MCL has larger cells with a high mitotic rate and fine chromatin. (E) These cases frequently overexpress p53 and are associated with a complex karyotype, including t(11;14).

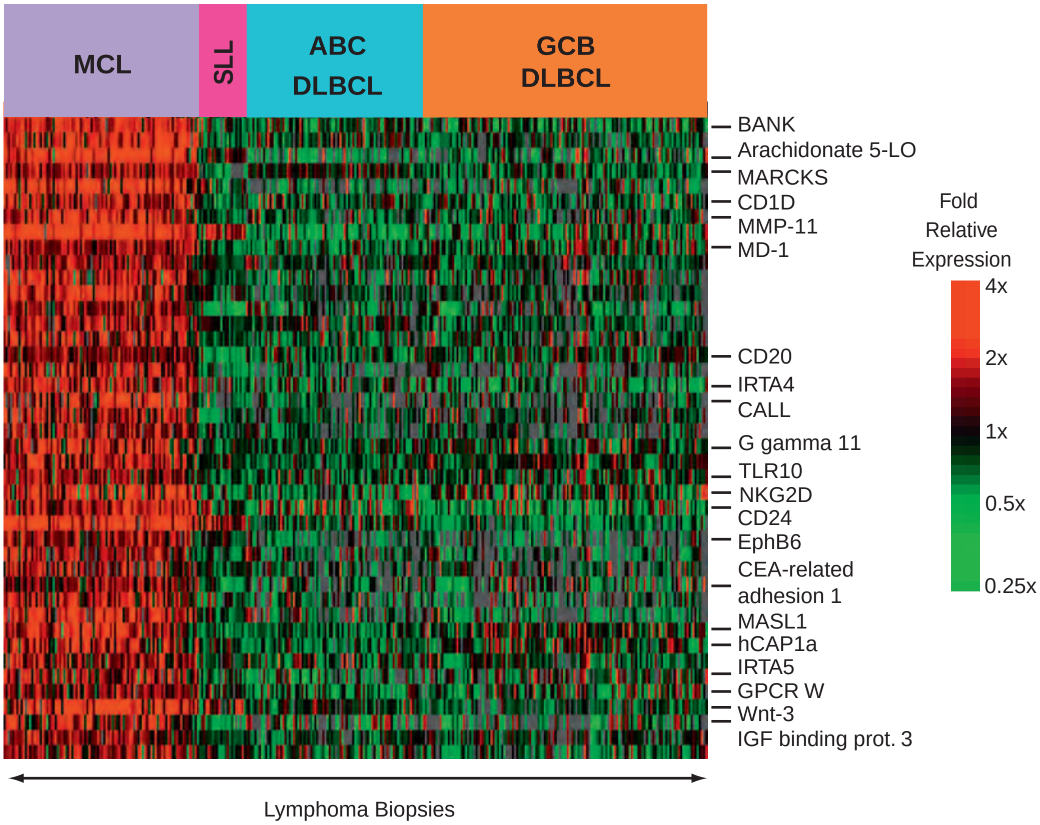

Figure 81.12 HIERARCHICAL CLUSTERING OF EXPRESSION MEASUREMENTS FROM 42 MANTLE CELL LYMPHOMA (MCL) SIGNATURE GENES THAT ARE MORE HIGHLY EXPRESSED IN MCL SAMPLES COMPARED WITH SMALL LYMPHOCYTIC LYMPHOMA (SLL), ACTIVATED B-CELL–LIKE (ABC) DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL), AND GERMINAL CENTER B (GCB) DLBCL SAMPLES. Each column represents a single lymphoma specimen, and each row represents expression of a single gene. *Red squares* indicate increased expression, and *green squares* indicate decreased expression relative to the median expression level according to the color scale shown. *(Reproduced from Fu K, Weisenburger DD, Greiner TC, et al. The proliferation gene expression signature is a quantitative integrator of oncogenic events that predicts survival in mantle cell lymphoma. Cancer Cell. 2003;3:185.)*

(Fig. 81.12). Whole exome/genome/transcriptome sequencing also reflects the idea that genomic alterations collaborate to upregulate activity of cell cycle machinery in MCL as loss of function alterations in *RB*, *ATM*, and *TP53* are found frequently in addition to cyclin D1 overexpression. *Wnt 3* is a consistently overexpressed gene in MCL, and abnormal Wnt signaling may be one way in which MCLs bypass negative feedback loops controlling differentiation. Proliferation in MCLs may also depend on Wnt–B-catenin signaling, but the impact of this pathway on patient survival or as a therapeutic target in MCL is unknown. Similar to ABC DLBCLs, the NFκB pathway is also active in MCL, and crosstalk between proliferation signaling between this pathway PI3K/AKT/mTOR and cell cycle signaling also appears to be important. Importantly, phosphatase and tensin homologue (PTEN), a molecule that has important roles in providing negative feedback to the mTOR pathway is also commonly deleted or acquires loss of function mutations in MCL. Taken together, these facts reinforce the fact that abnormalities in several diverse signaling pathways are required beyond t(11;14) for MCL to form. Further work is needed to define how to use these findings to build better prognostic models in this disease, and studies investigating the therapeutic utility of targeting these pathways are beginning.

OTHER NON-HODGKIN LYMPHOMAS

GEP and high-throughput sequencing have been applied to other lymphomas in manners similar to the subtypes already described. Important discoveries regarding other NHLs such as marginal zone lymphomas, lymphoplasmacytic lymphoma, and peripheral T-cell lymphomas (PTCLs), have refined our understanding of how these diseases develop (Fig. 81.13). Recurrent mutations in genes and involvement of molecular pathways governing control of apoptosis, cellular proliferation, and metabolism are recurrent themes in these NHL subtypes as well as those described earlier. In addition to being found in DLBCLs, *MYD88* L265P mutations have been reported in virtually all cases of lymphoplasmacytic lymphoma (Waldenström macroglobulinemia) and may serve (along with CXCR4 mutations) as a marker to differentiate this disease from other indolent lymphomas. *NOTCH2* mutations have been noted in a subset of marginal zone lymphomas and have been found in DLBCLs and other NHLs. Gene clusters have also been developed for T-cell lymphomas and identify PTCL subtypes such as angioimmunoblastic T-cell lymphoma (AITL) and hepatosplenic T-cell lymphoma as distinct molecular entities as compared to other PTCLs; this work also has shown upregulation of genes involved in NFκB signaling in AITL. A subset of PTCL is characterized by t(2;5) (p23;q35), which joins the anaplastic lymphoma kinase-1 gene *(ALK)* next to *NPM-1* at 5q35. This creates an aberrant tyrosine kinase that appears to have a number of downstream transforming effects. ALK positivity is generally associated with response to cytotoxic chemotherapy in PTCL; however, better molecular predictors of response are needed. Whereas NFκB gene signature expression also correlates to improved survival in PTCL, tumors that exhibit increased markers of proliferation are associated with poor outcomes, as in other NHLs. High-throughput genomic sequencing approaches have also revealed distinct patterns of somatic tumor mutations in PTCL subsets as compared to B-cell lymphomas. A recurrent mutation in *RHOA* (*RHOA* G17V), a small

Figure 81.13 T-CELL ONTOGENESIS AND COMMON MOLECULAR DRIVERS IN T-CELL LYMPHOID NEOPLASIA SUBTYPES THAT MIRROR CELL TYPE OF ORIGIN. Analogous to B-cell development and lymphoid malignancies that mirror underlying cell subsets, T-cell lymphoid malignancies can be conceptualized as subtypes that arise of cells at various stages of T-cell development and differentiation with each having distinct major drivers and phenotypes. Most of these entities are thought to arise from cells that have completed peripheral thymic migration and differentiation. *(Reproduced from Van Arnam JS, Lim MS, Elenitoba-Johnson KSJ. Novel insights into the pathogenesis of T-cell lymphoma. Blood. 2018;131(121):2320–2330.)*

GTPase involved in regulation of actin polymerization and stress fiber formation occurs in both PTCL subtypes and AITL and appears to correlate with gene signatures of NF-κB and MAP kinase activation, although the exact oncogenic role of RHOA in these tumors is unknown. Additionally, activating mutations in mediators of T-cell receptor (TCR) signaling including FYN kinase have been reported and point toward an oncogenic role for constitutively active TCR signaling in these lymphomas. Further studies are needed to define the roles of these mutations in T-cell lymphogenesis.

FUTURE DIRECTIONS

NHL represents a complex group of related neoplasms that have quite disparate molecular characteristics. Given the lack of modifiable risk factors and varied prognosis with standard treatment (chemoimmunotherapy), a better understanding of the processes driving NHL is needed. Advances in technology have recently allowed whole-genomic surveys to identify the role of altered genetics, transcription, and epigenetic regulation as contributors to the observed lymphoma phenotypes. This work will serve as the starting point for the unraveling of new diagnostic and prognostic markers, as well as therapeutic targets in a group of diseases in which such options are urgently needed.

CHAPTER 82

CLINICAL MANIFESTATIONS, STAGING, AND TREATMENT OF FOLLICULAR LYMPHOMA

Lucy Pickard and John G. Gribben

Non-Hodgkin lymphoma (NHL) refers to all malignancies of the lymphoid system with the exception of Hodgkin lymphoma. Development of the lymphoid system is a highly regulated process, characterized by differential expression of a number of cell-surface and intracytoplasmic proteins and antigen receptor gene rearrangements, somatic hypermutation, and class switching. Dysregulation of this orderly process can result in humoral deficiency, autoimmunity, or malignancy. The indolent B-cell lymphomas are mature peripheral B-cell neoplasms that exclude those diseases associated with an aggressive clinical course. Despite differences in cell of origin, molecular biology, clinical presentation, and clinical course, the indolent lymphomas share common features, including frequent localization to the principal lymphoid organs, a propensity for bone marrow (BM) infiltration and leukemic presentation, and generally an indolent clinical course. The classification of NHLs has been a challenge for pathologists as well as practicing physicians. A number of classifications have been proposed over the years, leading to considerable confusion and difficulty in comparison of outcomes of clinical trials performed using different pathologic classifications. The World Health Organization (WHO) lymphoma classification lists nearly 100 different types of lymphoid neoplasm.[1] This classification uses all available information such as morphology, cytochemistry, immunophenotype, and molecular genetics as well as clinical features. The WHO classification does not include the terminology *indolent lymphoma*. This is a clinical and not a pathologic term and defines those lymphomas that tend to grow and spread slowly and produce few symptoms. Indolent lymphomas represent 35% to 40% of NHLs, and follicular lymphoma (FL) is the most common of the indolent lymphomas.

EPIDEMIOLOGY

It is estimated that in 2021 more than 81,560 cases of NHL will be diagnosed in the United States, and more than 20,000 patients will die of their disease, making NHL the seventh most common cancer and the fifth most common cause of death from cancer (http://seer.cancer.gov/statfacts/html/nhl.html). NHL is extremely heterogeneous in its molecular pathophysiology, histology, and clinical course, and there are major differences in the incidence of subtypes in different geographic locations and among different racial and ethnic populations. This difference in geographic distribution is particularly striking for FL, and in the Western world, FL is the second most common lymphoma, comprising approximately 20% of all NHLs. The incidence of FL in the United States is approximately 2.7 cases per 100,000 persons per year and in Europe is approximately 3.14 cases per 100,000 persons per year.[2] The incidence appears stable over time. There is no strong sex preponderance. The incidence in Whites is approximately twice that of Black and Asian populations, and the disease appears less common in Central and South America. The incidence increases with age, and the median age of diagnosis is 65 years. Although most cases are sporadic, there is an increased incidence in family members of affected individuals, with a relative risk of 2.3 for siblings of patients.[3] Genome-wide association studies provide evidence for FL inheritance susceptibility. Multiple independent single nucleotide polymorphisms in human leucocyte antigen (HLA) class I and II genes on chromosome 6p21.3 were associated with susceptibility to FL.[4] Furthermore, FL risk was significantly associated with homozygosity at the HLA class II gene loci.[5]

Differentiation of complex environmental factors from true inherited factors remains difficult. The complexity of the epidemiology of NHL mirrors the complexity of the disease and that of the host immune system. Since lymphomas do not constitute a single disease, it should come as no surprise that there is no single etiologic factor. The influence on immune dysregulation of viruses, chemicals, radiation, diet, and aging remains unclear. Immune suppression leads to increased incidence of aggressive lymphomas but not usually indolent lymphomas.

PATHOGENESIS

FL (Fig. 82.1) is a neoplasm derived from germinal center (GC) B cells underlined by: histological appearance, with predominant follicular morphology and maintenance of GC architecture; immunophenotypical behavior, with FL B cells expressing GC markers BCL6$^+$ and CD10$^+$; and molecular characteristics, with evidence of ongoing class-switch recombination and somatic hyper mutation.[6] Bulk gene expression profiles of FL are closely related to normal GC light zone B cells,[7] therefore, the cell of origin is assumed to correspond with a GC B cell blocked at that stage of differentiation. A recent study examining cells at single cell resolution has shown that a continuum of dynamic cell states coexist within single patient biopsies, suggesting that FL cells have functional plasticity[8] as opposed to being “frozen” at a particular GC stage.

A hallmark of FL is the chromosomal translocation t(14;18)(q32;q21), placing the B cell lymphoma 2 (*BCL2*) gene under transcriptional control of the immunoglobulin heavy chain (*IGH)* locus, resulting in overexpression of the antiapoptotic protein BCL2.[9] Morphologically, the disease is composed of a mixture of centrocytes and centroblasts. The WHO third edition pathologic classification recommends grading in grades 1 to 3 according to the number of centroblasts (0 to 5, 6 to 15, and >15 per high-power field, respectively). Grade 3 was further subdivided into 3A (centrocytes still present) and 3B (sheets of centroblasts). An increased percentage of centroblasts is predictive of poor outcome. A problem with this classification is that it is poorly reproducible among pathologists. It is also clear that there are no major biologic or clinical differences between grades 1 and 2—whereas grade 3B FL is biologically distinct from grades 1 to 3A—and clinical and histological features suggest a closer relationship to diffuse large B cell lymphoma (DLBCL).[10,11] These considerations led to the recommendation to group together FL grade 1 to 3A as FL and create a new category called FL3B. The final classification combined FL grades 1 and 2 into one category (FL1–2 of 3) and made the distinction between FL3A and FL3B optional rather than mandatory.[12] The fourth edition of the WHO classification recognizes some distinctive clinical and genetic subtypes of FL, including primary duodenal FL and the pediatric type of FL that lacks the t(14;18) translocation and usually presents with localized disease. Several variants of FL that lack the t(14;18) have some distinctive

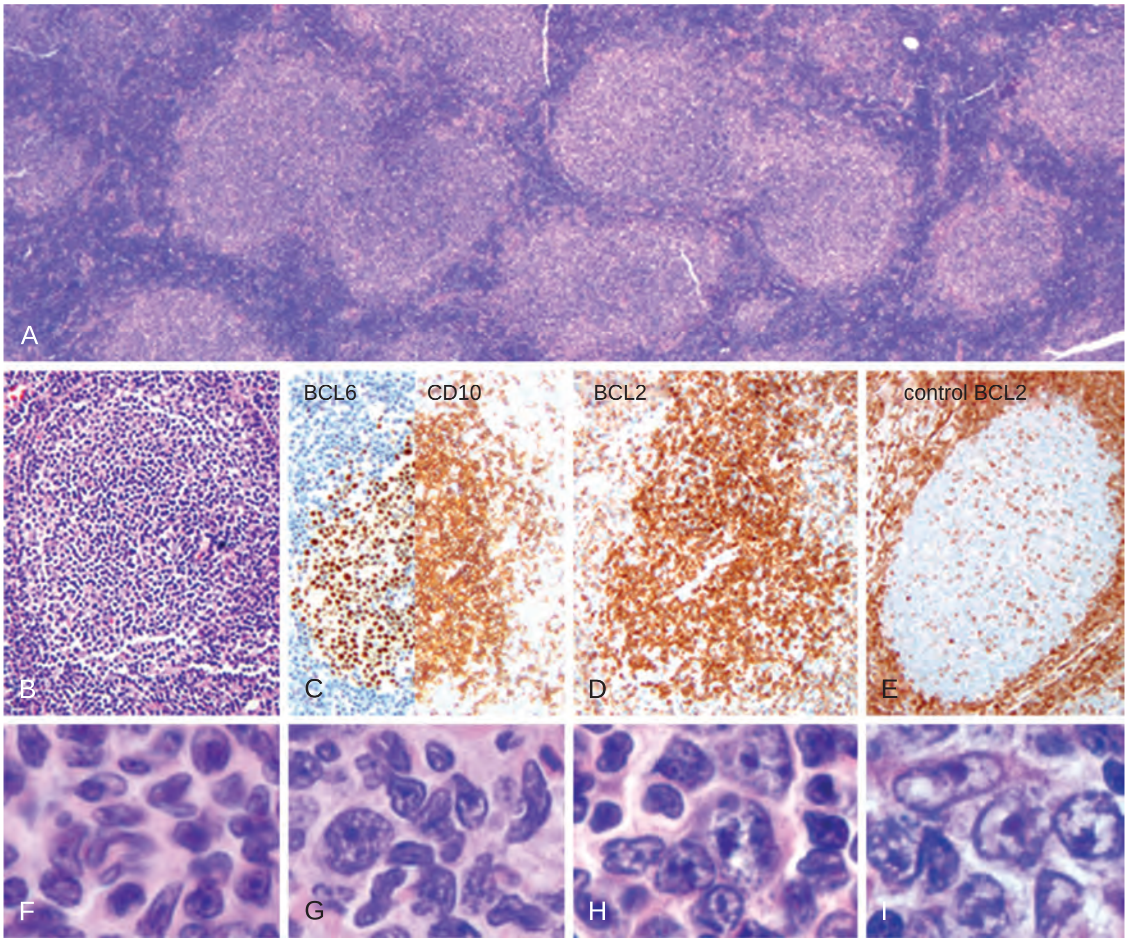

Figure 82.1 FOLLICULAR LYMPHOMA: MORPHOLOGIC AND IMMUNOPHENOTYPIC FINDINGS. (A) Low-power photomicrograph illustrates a lymph node involved by follicular lymphoma. The lymphoma cells grow in nodules or follicles that resemble the normal lymphoid follicles of a reactive lymph node. However, in the lymphomatous growth, the follicles are crowded, show back-to-back localization, and lack many of the features of their reactive counterparts. At higher power (B), the neoplastic follicles lack mantle zones, and the normal polarization of small and large germinal center cells (centrocytes and centroblasts, respectively), which occurs because of the cellular response to antigenic stimulation as it sweeps thorough the follicle. (C) The neoplastic follicles stain for the germinal center markers, BCL6 and CD10; however, they overexpress BCL2 (D) caused by the associated translocation t(14;18) involving the *IgH* gene and *BCL2*. BCL2 is not much expressed in normal germinal center B cells (E, control for comparison). Follicular lymphoma is graded by the number of large neoplastic cells (centroblasts) present among the smaller neoplastic cells (centrocytes) (F–I). The grading system is not entirely accurate, but provides some framework for subclassifying cases morphologically. Only 0 to 5 centroblasts per average field is grade 1 (F); between 6 and 15 is grade 2 (G); and greater than 15 is grade 3 A (H). Grades 1 and 2 are now considered together. When most of the cells in the neoplastic follicles are centroblasts without centrocytes the case is considered grade 3B (I) (see text).

features, e.g., predominantly diffuse FL with deletions of 1p36 that presents with localized bulky disease in the inguinal region.[13] A characteristic finding of t(14;18)-negative FL is an enrichment of activating mutations in the transcription factor *STAT6*, occurring in 57% of cases, compared with 10% in t(14;18) positive FL. *STAT6* mutations co-occurred with mutations in *TNFRSF14* and/or *CREBBP*, potentially revealing alternative oncogenic mechanisms in this FL subtype.[14]

FL lymphomagenesis is a complex multistep process with the acquisition of the t(14;18)(q32.3;q21.3) reciprocal translocation, generally considered the first hit in the oncogenic cascade.[15] However, there are multiple lines of evidence that t(14;18) in isolation is insufficient to propagate malignant transformation. Firstly, the translocation can be detected at low levels in the blood of healthy individuals.[16] Secondly, *BCL2* overexpression mouse models require additional genetic hits to promote overt tumor formation.[17] Finally, t(14;18) negative FL patients follow similar clinical trajectories.[13] Together, these data suggest GC B cells must acquire further oncogenic hits for complete transformation to FL.

The advent of next generation sequencing (NGS) technologies in the last decade—including whole genome, exome and targeted sequencing—have advanced our understanding of the genomic and epigenomic lesions that occur alongside the t(14;18) translocation. Compared to other malignancies, FL has an apparent “addiction” to epigenetic mutations, with greater than 90% of patients carrying one or more mutation in chromatin-modifying genes.[18–22] The histone lysine methyltransferase *KMT2D* is the most frequently mutated gene in FL affecting approximately 70% to 80% of cases.[18,20,21] Aberrations in the histone acetyltransferase (HATs) enzymes *CREBBP* and *EP300* occur in approximately 70% and 15% of FL cases, respectively.[18,20,22,23] The histone methyltransferase *EZH2* forms the catalytic component of the polycomb repressive complex 2 (PRC2) and is mutated in 20% to 25% of FL cases.[18,20,21] Other epimutations occur in genes involved in chromatin remodeling, such as *ARID1A* and the linker histones (*HIST1H1B-E*), occurring in approximately 10% and 30% of cases, respectively.[18,24]

Inactivating mutations of *KMT2D*, *CREBBP*, and *EP300*, and gain-of-function mutations of *EZH2*, result in a shift from active to repressive marks, leading to aberrant repression of gene transcription and interference with transcriptional programs that regulate normal GC B cell selection, differentiation, and exit.[25,26] Consequently, aberrant GC B cells accumulate resulting in exposure to further genomic instability, favoring their malignant transformation. Epimutations alone do not appear sufficient to initiate FL but require dysregulation of BCL2 expression to induce lymphomagenesis.[27–29] Other recurrently disrupted pathways in FL include: immune recognition (*TNFRSF14, CTSS*); BCR-NFκB (*CARD11, TNFAIP3, MYD88*); mTOR (*RRAGC, ATP6AP1, ATP6V1B2, SESTRIN1*); and JAK-STAT signaling (*STAT6, SOCS1*).[18,20–23,30–33] The major mutations seen in FL are listed in Table 82.1.[18–21,23,25,30,33–45]

TABLE 82.1 **Mutations in Follicular Lymphoma**

Gene Name	*Abbreviation*	Location	Frequency at Diagnosis (%)
Lysine methyltransferase 2D	*KMT2D*	12q	80–90
CREB binding protein	*CREBBP*	16p	33–70
Enhancer of zeste 2 polycomb repressive complex 2 subunit	*EZH2*	7q	7–25

Cyclin dependent kinase inhibitor 2 A	*CDKN2A*	9p	46
Early B cell factor 1	*EBF1*	5q	7–17

FL cells exist within a tumor microenvironment milieu of nonmalignant immune, stromal, and extracellular components, and are critically reliant on micro-environmental signals for proliferation and survival. A detailed review of the complex interactions between these components is beyond the scope of this chapter, but readers can refer to specific reviews on this topic.[46,47]

CLINICAL PRESENTATION

The majority of patients present with lymphadenopathy in one or more sites. Patients with FL often present with a long history of having noted painless, enlarged lymph nodes (LN) over a number of years before presentation. Lymphadenopathy may wax and wane, and spontaneous remissions can occur, albeit rarely.[48] Disease transformation to a more aggressive histologic type confers inferior outcomes, especially early transformation.[49]

Extranodal disease is relatively common and can affect any organ. The most common sites of extranodal disease include the BM, skin, gastrointestinal tract, and bone. Symptoms may be nonspecific or related to the site of disease involvement. Many patients are asymptomatic, but some, particularly those with bulky disease may present with B symptoms defined as fever, drenching sweats, or weight loss of more than 10% of body weight. Patients may present with evidence of bowel obstruction from intraabdominal lymphadenopathy, and retroperitoneal disease may manifest as obstructive uropathy. Inguinal disease may cause compression of the venous system with deep venous thrombosis. Central nervous system involvement can occur, but is uncommon in FL.

DIAGNOSIS OF FOLLICULAR LYMPHOMA

Suggested guidelines for the diagnosis of lymphomas have been outlined by the National Comprehensive Cancer Network (guidelines available at http://www.nccn.org/) and by the European Society for Medical Oncology.[50] In all cases possible, diagnosis should be confirmed by excisional biopsy of an accessible LN and review by an expert hematopathologist with expertise in lymphoma diagnosis. In patients without easily accessible peripheral nodes, computed tomography (CT) or ultrasound-guided biopsies are typically well tolerated. Fine-needle aspiration is not appropriate for diagnosis in these conditions, and sufficient material must be obtained for adequate histologic review, immunophenotyping, and genetic studies, as required for diagnosis and assay for prognostic markers. When possible, consent should be obtained for the procurement, storage, and use of excess tissue from LN biopsies—at the time of presentation and at each subsequent relapse of disease—for research purposes to investigate the molecular biology of these diseases as new technologies and findings become available.

Initial essential investigations are shown in Table 82.2. Physical examination should include careful examination of all peripheral LN groups, including the cervical, supraclavicular, axillary, and inguinal chains, and examination of the Waldeyer ring. Abdominal examination should focus on evaluation of any intraabdominal masses, with particular attention paid to detection of enlargement of the liver or spleen. The skin should be carefully examined. Patients may present with pleural or pericardial effusions, although this is less common than in the aggressive lymphomas. Laboratory investigations should include a complete blood count to evaluate for cytopenias, which may be evidence of BM infiltration or of autoimmunity. A white blood count with differential and examination of the peripheral blood smear may elucidate leukemic involvement with disease. Baseline electrolytes including calcium and phosphate, creatinine, and liver function tests are important to determine organ dysfunction that may be related to direct infiltration by lymphoma. Elevation of lactate dehydrogenase (LDH) is an important prognostic factor and may be a useful indicator of transformation from indolent to aggressive lymphoma. Hepatitis B testing is essential as patients will likely require subsequent treatment with anti-CD20 monoclonal antibody therapy.

TABLE 82.2 Initial Evaluation of Follicular Lymphoma

- Physical examination with attention to peripheral nodes, abdomen
- Complete blood count, evaluation of peripheral blood
- Urea, creatinine and electrolytes
- Liver function tests; LDH; β_2-microglobulin

- LN biopsy with review by an expert lymphoma histopathologist
- Bone marrow biopsy/aspirate
- Hepatitis B (surface antigen and core antibody), hepatitis C and human immunodeficiency virus (HIV)
- Other studies as indicated

CT, Computed tomography; *LDH*, lactate dehydrogenase; *LN*, lymph node; *PET*, positron emission tomography.

TABLE 82.3 Ann Arbor Staging

Stage	Criteria
I	Involvement of 1 lymph node (I) or 1 extralymphatic organ or site (IE)
II	Involvement of ≥2 lymph nodes on same side of diaphragm (II) or localized extralymphatic organ or site and ≥1 involved lymph node on same side of diaphragm (IIE)
III	Involvement of lymph nodes on both sides of diaphragm (III) or same side with localized involvement of extralymphatic site (IIIE), spleen (IIIS), or both (IIIS+E)
IV	Diffuse or disseminated involvement of 1 extralymphatic organ or tissues with or without lymph node enlargement

Staging workup also includes a CT scan of the chest, abdomen, and pelvis, and increasingly, a positron emission tomography (PET) scan to direct sites for biopsy and to help rule out histologic transformation. Particular attention should be paid to sites of bulk disease and to the number of involved sites. BM biopsy provides essential information and should be performed routinely as it is required for staging and prognostication of disease. Liver biopsy may be indicated based upon abnormal imaging or laboratory testing.

STAGING

The staging of NHL uses the Ann Arbor Classification (Table 82.3). Functional and anatomical imaging with positron emission tomography-computed tomography (PET-CT) is recommended as the standard for staging fluorodeoxyglucose (FDG)-avid nodal lymphomas.[51] FDG PET-CT may detect additional nodal and extranodal sites of disease when compared with standard CT. In a retrospective study, more nodal and extranodal lesions were detected by FDG PET-CT when compared with CT, and 11% of patients were upstaged from limited stage disease (I/II) to advanced stage disease (III/IV).[52] PET-CT staging may also contribute to improved prognosis in patients with stage I disease treated with involved field radiotherapy, likely due to more accurate identification of stage I disease.[53] However, PET-CT is of limited value for the detection of BM involvement. A BM aspirate and biopsy is still required if documentation of BM involvement by FL will have an impact on clinical management.[54]

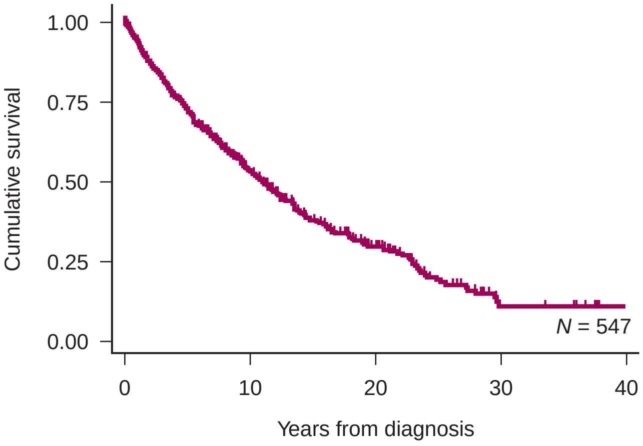

Figure 82.2 OVERALL PROBABILITY OF SURVIVAL OF PATIENTS WITH FOLLICULAR LYMPHOMA TREATED AT ST. BARTHOLOMEW'S HOSPITAL.

NATURAL HISTORY

Until recently, there was little evidence that the natural history of FL had changed over the last 30 years from the median survival of 10 years from diagnosis.[48] The survival of patients with FL presenting at St. Bartholomew's Hospital in London is shown in Fig. 82.2. The introduction of monoclonal antibodies, in combination with chemotherapy, has led to an improvement in survival. The median overall survival (OS) for FL now extends to 15 to 20 years.[55] However, it is still considered as an incurable malignancy. The natural history of FL is characterized by a protracted, relapse-remitting course, with each disease-free period becoming progressively shorter, leading to eventual treatment refractoriness. Importantly, significant clinical heterogeneity exists among patients, which poses dilemmas for treatment decision-making. Progression of disease within 24 months of initial immunochemotherapy (POD-24) occurs in 10% to 20% of patients and is associated with poor outcomes, with only 50% of patients alive after 5 years.[56] Similarly, transformation to high-grade lymphoma confers inferior outcomes, especially early transformation.[49]

There is, therefore, a need for prognostic markers that can help identify those patients who will have a good or poor prognosis. A number of prognostic scoring systems have been developed, with the aim of dichotomizing patients into groups to identify high-risk patients. The follicular lymphoma international prognostic index (FLIPI) is a five-factor prognostic index based upon the clinical characteristics age, stage, number of nodal sites, hemoglobin, and LDH level (Table 82.4). The index defines three prognostic risk groups of an almost equal numbers of patients.[57] This tool is useful in assessing the likely need for early treatment of patients and potential outcome, as well as in comparing the outcomes of different clinical trials. A revised FLIPI2 (incorporating β_2-microglobulin, diameter of largest LN, BM involvement, and hemoglobin level) may better discriminate the outcome for patients requiring treatment, with 5-year OS of 96% for low-risk patients, 80% for intermediate-risk patients, and 50% for high-risk patients.[58] Therefore, it is important to include the features required for calculation of FLIPI and FLIPI2 at the time of diagnosis.

The m7-FLIPI score combines clinical features (FLIPI and performance status) with the mutation status of seven genes *(EZH2, ARID1A, MEF2B, EP300, FOXO1, CREBBP, CARD11)*.[25] It was validated for patients receiving rituximab with CHOP or CVP chemotherapy. However, it was not prognostic for patients receiving immunotherapy in combination with bendamustine.[59,60] In addition, the m7-FLIPI was not prognostic for FL patients who received rituximab monotherapy.[61] GEP 23, a model derived from the expression profile of 23 genes, appears to be able to risk stratify FL patients, although this requires prospective validation.[62]. However, it remains uncertain by what means these prognostic tools can be used to inform clinical decisions on how and when to treat patients. These scores

TABLE 82.4 Factors Having Prognostic Significance in the Follicular Lymphoma International Prognostic Index (FLIPI)[57] and FLIPI2[58]

FLIPI

Parameter	Adverse Factor	HR
Age	≥60 years	2.38
Ann Arbor stage	III–IV	2.00
Hemoglobin level	<120 g/L	1.55
Serum LDH level	>ULN	1.50
Number of nodal sites	>4	1.39

FLIPI2

Parameter	Adverse Factor	HR (in Final Model)
β_2-microglobulin	>ULN	1.5
BM involvement	BM involvement with disease	1.59
Hemoglobin level	<120 g/L	1.51
Largest diameter of LN	>6 cm	1.66
Age	>60 years	1.38

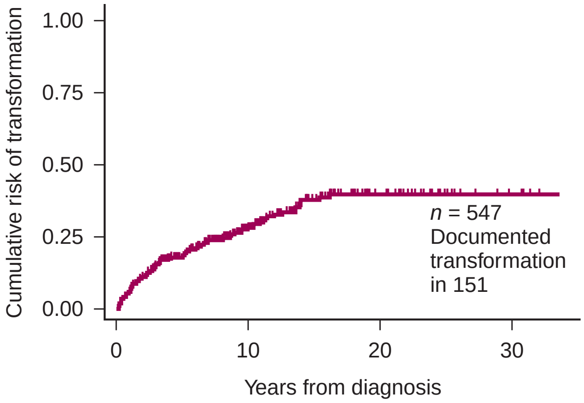

Figure 82.3 PROBABILITY OF RISK OF TRANSFORMATION OF PATIENTS WITH FOLLICULAR LYMPHOMA.

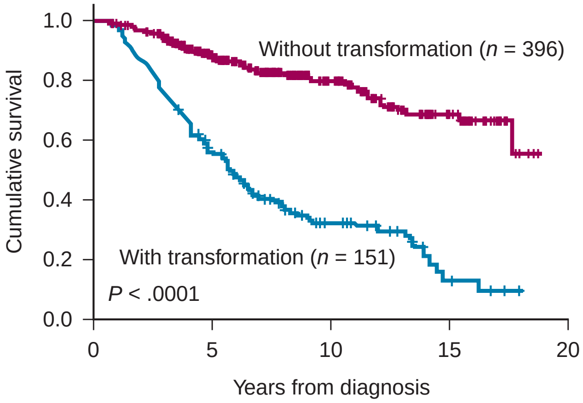

Figure 82.4 OVERALL PROBABILITY OF SURVIVAL OF PATIENTS WITH FOLLICULAR LYMPHOMA WHO HAVE AND HAVE NOT UNDERGONE HISTOLOGIC TRANSFORMATION.

need to be revalidated for use with new therapies, in an ever evolving treatment landscape. In addition, these scores cannot necessarily identify high-risk patients more reliably than simpler baseline assessments, such as total metabolic tumor volume (TMTV) by PET-CT[63] or PRIMA-PI, which uses serum B2M and the presence/absence of BM involvement.[64]

An important factor for the prognosis of FL is whether patients undergo histologic transformation.[65] The actuarial risk of FL undergoing histologic transformation in the database of the patients treated at St. Bartholomew's Hospital is shown in Fig. 82.3.The survival of patients with and without transformation is shown in Fig. 82.4. Despite a considerable body of information on the pathologic and molecular events associated with histologic transformation, the pathogenesis of transformation remains elusive, and the molecular events that have been identified have not been translated into changes in clinical practice. Our current, "one approach treats all" particularly underserves the high-risk FL population. A major research focus is attempting to identify patients at high risk of histologic transformation early in their clinical course, but this is not yet possible. The outcome of patients who undergo transformation after already having received multiple lines of therapy remains poor, but for those patients who undergo transformation and receive their first therapy for the transformed disease, the use of chemo-immunotherapy has led to a significant improvement in prognosis.

TREATMENT OF FOLLICULAR LYMPHOMA

For most cases of FL, the goal of therapy has been to maintain the best quality of life and treat only when patients develop symptoms. Any alteration to this approach requires demonstration of improved survival with early institution of therapy, or identification of criteria that define patients sufficiently "high-risk" to merit early therapy. There are many available therapies and no consensus on an optimal first-line or relapse treatment. Despite the lack of any data demonstrating benefit for early therapy, patients are being treated earlier in their disease course. There is no clear-cut treatment pathway for patients with FL, and although we have a good evidence base to decide on a particular treatment, there are little or no data regarding the optimal sequencing of treatment approaches in this disease. In the absence of such data, treatment choices remain empiric and should always involve discussion regarding patient choice and the goal of therapy. This is becoming even more complicated because many novel agents are either approved or are in clinical studies, particularly novel monoclonal antibodies and agents that alter the B cell receptor signaling pathways or anti-apoptotic pathways. The impact of these new agents on practice will be dependent upon the results of the ongoing clinical trials.

Multiple treatment approaches exist for advanced stage low-grade lymphomas, and these patients are best treated in the setting of clinical trials. Options range from a "watch and wait" expectant management approach, to a single agent chemotherapy (rarely used today) or a monoclonal antibody therapy with anti-CD20 antibodies, to a combination chemo-immunotherapy, with use of autologous or allogeneic stem cell transplantation (SCT) or chimeric antigen receptor (CAR) T cells (Table 82.5). Patients remaining on an expectant course should be documented every 3 to 6 months for 5 years, and then annually if stable, with history, physical exam, and blood counts including LDH. Special attention should be paid to any change in symptoms that might be suggestive of transformation, as these are an indication for a repeat biopsy to examine for histologic evidence to confirm transformation. Repeat scanning is not routinely performed unless this is indicated by symptoms or signs.

Since there is no clearly defined treatment algorithm for most patients with FL, eligible patients should be included whenever possible in clinical trials. This ensures delivery of optimal care and helps inform design of subsequent trials, hopefully leading to a cure. Information on available clinical trials can be found at http://www.clinicaltrials.gov. (See box on Management of Follicular Lymphoma.)

High-dose chemotherapy plus autologous/allogeneic stem cell transplantation
Reduced intensity conditioning allogeneic transplantation.
Chimeric antigen receptor T cells
Palliative radiotherapy

MANAGEMENT OF FOLLICULAR LYMPHOMA

Patients most often present with asymptomatic lymphadenopathy. The diagnosis should be made by excisional biopsy and reviewed by an expert hematopathologist. In the absence of symptoms requiring treatment or bulky lymphadenopathy, an expectant "watch and wait" approach is the treatment of choice. While in this phase of treatment, patients should be followed every 3–6 months for history, physical, and laboratory examination with radiologic restaging as clinically indicated. Once a decision to treat has been made, there is no clear treatment algorithm and a number of treatment options are available. The treatment goal, whether palliative or potentially with curative intent, is dependent upon the age and performance status of patients. Enrollment in a clinical trial should be the treatment of choice. For younger patients in whom high-dose therapy may be indicated later in their disease course, it is best to avoid profoundly myelotoxic regimens. Rituximab maintenance therapy in first remission given every 2 months for 2 years has been demonstrated to improve progression-free, but not overall survival. The role of maintenance therapy in first remission using interferon-α remains controversial. The choice of therapy after first relapse is also dependent upon the goal of therapy, but is also dependent upon the previous therapy given, response, and duration of response. Autologous or allogeneic stem cell transplantation has a role to play in selected younger patients with this disease, and chimeric antigen receptor (CAR) T cells are now licensed for treatment of multiply relapsed FL.

WHEN TO INSTITUTE THERAPY

Stage I–II Disease

Involved site radiation therapy is the preferred treatment for the approximately 10% of patients who present with limited stage, nonbulky disease. Treatment with photons, electrons, or protons may be appropriate depending on clinical circumstances. This treatment option is offered with curative potential[52,66] but must be weighed against the potential toxicity of the radiation therapy to other tissues. In patients with large tumor burden or with other adverse risk factors, systemic therapy is indicated. There is no proven role of radiation consolidation therapy.

Bulky Stage II and Stage II/IV Disease

Expectant management is the treatment of choice for asymptomatic patients with low-bulk disease until clear indications for initiation of treatment are seen, except for those patients enrolled in a clinical trial assessing the impact of early therapy. This approach is based upon the demonstration of no survival advantage for institution of immediate treatment, compared with deferred treatment until time of progression.[67] Three randomized trials, performed in the pre–rituximab era, confirmed no survival benefit for early therapy.[68–70] In the National Cancer Institute study, in 104 newly diagnosed patients with FL, deferred treatment was compared with immediate treatment with ProMACE-MOPP followed by total nodal irradiation. An updated analysis of this data is long overdue, but there was no difference in OS between the two arms at the time of the last analysis.[68] The Groupe pour l'Etude de Lymphome Folliculaire (GELF) used defined criteria for patients for whom immediate therapy was not felt to be indicated (Table 82.6) and randomized 193 patients to deferred treatment or to receive prednimustine 200 mg/m^2/day for 5 days per month for 18 months or IFN-α 5 million units (MU)/day for 3 months followed by 5 MU three times per week for 15 months.[69] The median OS time was not reached and was the same in all three arms of the study. The British National Lymphoma Investigation (BNLI)[70] compared treatment in 309 patients with asymptomatic advanced-stage, indolent lymphoma in whom 158 patients were randomized to receive immediate therapy with oral chlorambucil 10 mg/day continuously and 151 patients were randomized to deferred treatment until disease progression (see Table 82.6). In both arms, local radiotherapy to symptomatic nodes was allowed. There was no difference in OS or cause-specific survival between the two groups with median follow up of 16 years. A subsequent multicenter study examined whether rituximab could delay the need for chemotherapy or radiotherapy compared with watchful waiting.[72] A total of 463 patients were randomly assigned to watchful waiting, rituximab 375 mg/m^2 weekly for 4 weeks (rituximab induction), or rituximab induction followed by a maintenance schedule of 12 further infusions given at 2-monthly intervals for 2 years (maintenance rituximab). The rituximab induction arm was closed early, and the study continued to accrue to the other two arms. There was a significant difference in the time to start of next treatment, with 46% of watchful waiting patients still not needing treatment at 3 years compared with 88% in the maintenance rituximab group ($P < .0001$) and 78% in the rituximab induction group.

A major clinical trial question is whether identification of clinical or molecular risk factors can guide which patients are candidates for early therapy. A survival predictor score has also been developed from gene expression profiling studies.[73] This study demonstrated that gene expression from different immune cell components has a substantial impact on patient survival; FL cases enriched with genes expressed by macrophages and follicular dendritic cells showed an inferior outcome. Whereas it is to be hoped that in the future guidelines for treatment will be based upon clinical staging systems, genetic

TABLE 82.6 **Criteria for Delaying Treatment**

GELF[71]

All of the following

- Maximum diameter of disease <7 cm
- Fewer than 3 nodal sites
- Absence of systemic symptoms
- Spleen <16 cm on CT
- No significant effusions
- No risk of local compressive symptoms
- No circulating lymphoma cells or marrow compromise (Hb ≤10 g/dL, WBC <1.5 or platelets <100,000/dL)

BNLI[70]

Absence of all of the following

- B symptoms or pruritus
- Rapid generalized disease progression
- Marrow compromise (Hb ≤10 g/dL, WBC <3.0 or platelets <100,000/dL)
- Life-threatening organ involvement
- Renal infiltration
- Bone lesions

profiles, and immune response signatures, it has not yet been established which factors help us to decide who should have immediate therapy. This may well have practical implications, since it has been demonstrated that patients who progress within 2 years of diagnosis have poorer outcome[56,74] and might well benefit from earlier institution of treatment.

Although there are little available data to suggest that we should change our practice of "watch and wait" for the asymptomatic low-bulk patients, data suggest that this practice is becoming much less common in the United States.[75] The National Lymphocare study is a prospective observational study designed to assess presentation, prognosis, treatment, and clinical outcomes in newly diagnosed FL. The treating physician determines management according to clinical judgment, with no prescribed treatment regimen, and data regarding histology, stage, therapy, response, relapse, and death are recorded. Among 2708 patients, enrolled at 265 centers, only 17.7% of patients were initially observed, and of these, 22% received active therapy within 1 year and 31% within 2 years, the majority with chemoimmunotherapy. This observation is in stark contrast to the data from the BNLI study, which demonstrated that, when censored for non-lymphoma death, 19% of patients and 40% of those older than 70 years who were randomized to expectant management still did not require therapy after 10 years.[70]

TREATMENT APPROACHES

Treatment is indicated in patients with symptomatic disease, bulky lymphadenopathy and/or splenomegaly, risk of local compressive disease, marrow compromise, or steady progression of disease. Once indicated, numerous treatment approaches are available (see Table 82.5). The concept that the treatment approach can be to "do nothing" or discuss an approach with considerable morbidity and mortality, including approaches such as SCT, is a confusing one for the newly diagnosed patient (as well as for the physician). Considerable consultation time is required to review available treatment approaches. Staging of response in FL is by the revised response criteria.[76] Depending on the treatment approach used, restaging after two to three cycles of therapy can be useful to ensure responsiveness, and the patient is then fully restaged after completion of therapy. Whereas curative approaches are being sought in aggressive lymphomas, the failure to achieve complete remission (CR) or complete eradication of disease does not have the same implication in FL as in aggressive lymphomas. Depending upon the goal of therapy, a partial remission (PR) may be a sufficient response to alleviate symptoms.[77–80]

In the absence of a clear standard of care with curative potential, the optimal first-line treatment remains enrollment in randomized clinical trials wherever possible. In the National Lymphocare study,[81] academic sites are more likely than community sites to treat patients on clinical trials (12% vs. 4%), but it is lamentable that only 6% of patients overall were enrolled in clinical trials. For patients who are not eligible for or who refuse entry into clinical trials, there is data demonstrating higher response rates and longer duration of responses, and perhaps improved survival with chemoimmunotherapy. Many investigators favor alkylator over fludarabine-based regimens for FL, based upon concerns regarding the ability to obtain stem cells for later use for autologous SCT (ASCT) or CAR-T therapy in fludarabine-treated patients.[82] It is suggested that more aggressive first-line therapy should be offered to patients who progress within 1 year of presentation, since these patients have a worse outcome.[71] Older adult patients or those with poor performance status may remain candidates for single-agent chlorambucil, although this is given most often in combination with rituximab. Single-agent rituximab therapy is appropriate for patients who choose to avoid chemotherapy and is a reasonable treatment choice based upon the results of clinical trials of standard or prolonged induction with or without maintenance therapy with rituximab. Although data suggest a survival advantage with the use of interferon (IFN)-α in combination with chemotherapy, this agent is more rarely used. Optimal results are seen when radioimmunoconjugates are used earlier in the disease course. On the basis of results showing no benefit for ASCT, there is no indication for the use of high-dose therapy and SCT in first remission in FL unless as part of a clinical trial.

Chemo-immunotherapy is now the treatment of choice for FL. No randomized trials demonstrate a benefit for the addition of anthracyclines, but cyclophosphamide, adriamycin, vincristine, prednisone, and rituximab (R-CHOP) is heavily favored over cyclophosphamide, vincristine, prednisone, and rituximab (CVP-R) or fludarabine-based regimens. Following demonstration of improved outcome using bendamustine plus rituximab (BR), compared with R-CHOP[83] or to fludarabine plus rituximab,[84] the use of BR has greatly increased. BR also has improved tolerability and can be given without the complication of hair loss. Choice to initiate therapy was associated with FLIPI, stage, and grade, but FLIPI was not associated with decision to use a specific treatment approach. In the Lymphocare study, significant regional and center differences are observed and strongly suggest that physician preference is the predominant factor that drives initial therapy. For example, initial "watch and wait" was used in 31% of patients in the Northeast, but in 13% of patients in the Southeast, whereas fludarabine-based chemoimmunotherapy was used in 18% of patients in the Southwest and in only 3% of patients in the Northeast.

Finally, the RELEVANCE study randomized previously untreated patients with advanced FL to receive either rituximab in combination with lenalidomide, or rituximab-chemotherapy, with both arms receiving maintenance rituximab. The 3-year PFS was 77% and 78%, respectively, which demonstrated the potential of a chemotherapy-free frontline therapy[85] (NCT01476787).

Alkylating Agents

The alkylating agents, chlorambucil and cyclophosphamide, with or without prednisone and CVP or CHOP, and other alkylator-based combination chemotherapy regimens have been the standard of therapy for decades. Single-agent alkylators at different doses and schedules produce overall response (OR) rates of 50% to 75% in

FL.[86,87] Comparable response rates, but higher CR rates with longer progression-free survival (PFS) are seen with CVP compared with chlorambucil, but have no survival advantage.[88] The addition of anthracyclines has not improved the response rate or duration of the response,[71,89] but its use may be associated with a lower risk of histologic transformation.[68,90]

Purine Analogues

The purine analogues have been studied extensively in various types of indolent lymphoma. Fludarabine monotherapy produces response rates of 65% to 84%, with 37% to 47% CR in previously untreated patients with FL.[91] In a randomized trial of 381 previously untreated indolent lymphoma patients, CR rates were higher with fludarabine than CVP.[92] Fludarabine combinations result in increased response rates, with 89% CR rate in an Eastern Cooperative Oncology Group (ECOG) trial combining fludarabine and cyclophosphamide.[93] Fludarabine and mitoxantrone (FM) produced a 91% overall response rate (ORR), 43% CR, and 2-year disease-free survival (DFS) of 63%.[94] A higher CR rate was seen with FM (68%) compared with CHOP (42%) in a randomized trial.[95] The use of alkylator-based regimens or purine analog–based regimens appears to vary geographically, suggesting personal preference for the use of regimens in which the clinician has experience, rather than alterations of practice based on the results of the published studies.

Bendamustine

Bendamustine is a potent alkylating agent that shows substantial efficacy in NHL patients, including those with FL. Bendamustine is highly effective in rituximab-refractory FL and in patients whose disease is refractory to other alkylating agents. It has also demonstrated considerable efficacy in previously untreated FL, both alone and in combination with rituximab or other chemotherapeutic agents.[96,97] Increased understanding of the mechanisms of action of bendamustine and the efficacy of bendamustine in combination with rituximab in newly diagnosed or relapsed/refractory FL[83,84] has led to investigation of other combinations. Ongoing studies are examining bendamustine with other agents.

Biologic Therapy

IFN-α is approved by the Food and Drug Administration (FDA) for the treatment of advanced stage FL in combination with anthracycline-based chemotherapy, based upon improved survival in clinical trials[57,98,99] and meta-analysis of phase III trial data.[100] IFN-α was more widely used in Europe than in the United States, where it is believed that its toxicity profile outweighs potential benefit. In the Southwest Oncology Group (SWOG) study,[101] 571 patients with stage III and IV indolent lymphoma were treated with ProMACE-MOPP, and 279 responding patients were randomized to 24 months of observation versus treatment with IFN-α. No statistically significant difference in PFS or OS was observed between observation and IFN-α groups after 4 years.

Monoclonal Antibody Therapy

Monoclonal antibodies remain the most exciting agents to emerge in the treatment of FL. The most widely used monoclonal antibody is rituximab, a chimeric unconjugated antibody against the CD20-antigen. It is licensed by the FDA[102] and the European Agency for the Evaluation of Medicinal Products[103] for treatment of patients with relapsed or refractory CD20-positive low-grade or FL; for the first-line treatment of CD20-positive FL in combination with CVP chemotherapy; and for the treatment of CD20-positive low-grade NHL in patients with stable disease or who achieve a PR or CR following first-line treatment with CVP chemotherapy. The use of this agent has a profound effect in finally leading to improvement in patient survival in FL.[104–106]

Following phase I studies,[107] rituximab at a dose of 375 mg/m^2 weekly for 4 weeks was selected for the pivotal phase II trial.[108] Although this remains the standard dose, the optimal dose and schedule of rituximab is still unknown. In relapsed patients with FL, OR to rituximab monotherapy was 60% with a median PFS for responders of 13 months. Factors associated with lower response rates include chemoresistant disease,[108] bulky disease,[109] and treatment late in the disease course.[110] OR was 73% in previously untreated patients with low-bulk disease,[111] and some of these patients needed no further treatment and had no evidence of polymerase chain reaction (PCR) detectable minimal residual disease (MRD) after 7 years.[112] Extended use with 8 weeks instead of 4 is associated with improvement in OR and duration of response.[113] Comparable or even longer durations of response have been observed with retreatment.[114]

A number of trials in front-line and in relapsed/refractory patients have investigated the potential benefits of extended or maintenance rituximab treatment,[80,115–119] and all demonstrated prolonged time to progression in patients receiving maintenance rituximab (Table 82.7). The results from the E1496 randomized trial from ECOG and Cancer and Leukemia Group B comparing CVP alone to CVP followed by rituximab in patients with advanced-stage FL demonstrated that addition of rituximab maintenance significantly improved OS[115] and led to FDA approval for rituximab therapy in patients responding to CVP chemotherapy. The results of the primary rituximab and maintenance (PRIMA) study demonstrated an advantage in PFS for maintenance rituximab therapy offered after initial chemoimmunotherapy.[119]

Chemoimmunotherapy

In a phase II study, 40 patients with indolent lymphoma were treated with six infusions of rituximab (375 mg/m^2 per dose) in combination with six doses of CHOP chemotherapy (R-CHOP),[121] and OR was 95%, with 55% CR. In a phase II study of 40 patients with indolent lymphomas, rituximab in combination with fludarabine produced OR of 90%, with 80% CR, with similar response rates in treatment-naive and previously treated patients.[122]

A number of randomized trials show a benefit for the use of rituximab with chemotherapy compared with chemotherapy alone (Table 82.8).[77,78,123,124] Each study showed an improvement in time

TABLE 82.7 **Studies of Rituximab Maintenance Therapy in Indolent Lymphomas**

Trial	Disease Setting	Diseases Included	Previous Therapy
ECOG[115]	1st line	Follicular Small lymphocytic	CVP
SAKK[80]	1st line Relapsed/refractory	Follicular Mantle cell	Rituximab

CHOP, Cyclophosphamide, adriamycin, vincristine, prednisone; *CVP*, cyclophosphamide, vincristine, prednisone; *CHVP-IFN*, cyclophosphamide, doxorubicin, teniposide, prednisone, IFN-α; *CR*, complete remission; *FU*, follow-up; *MCP*, MCP received a combination of mitoxantrone 8 mg/m^2 intravenously on days 1 and 2, chlorambucil 3 × 3 mg/m^2 orally on days 1 to 5, and prednisolone 25 mg/m^2 orally on days 1 to 5; *NR*, no response; *OR*, overall response; *R-CHOP*, rituximab plus CHOP; *R-CHVP-IFN*, rituximab plus CHVP-IFN; *R-CVP*, rituximab plus CVP; *R-MCP*, rituximab plus MCP; *TTF*, time to treatment failure.

to treatment failure and more recent follow-up data suggests improved OS in patients treated with chemo-immunotherapy compared with chemotherapy alone. A meta-analysis of these trials demonstrates that OS, OR, and disease control are significantly better in those on chemoimmunotherapy compared with chemotherapy for FL and mantle cell lymphoma (MCL).[125] Data from the German low grade study group (GLSG) suggest that it is the addition of rituximab that has led to the recent improvement in survival of patients with FL.[105] An independently assessed analysis of the clinical benefits provided by rituximab in relation to cost concluded that it is highly cost effective.[126]

The largest FL trial reported to date is the PRIMA study (NCT00140582).[119] This study enrolled 1217 patients to receive initial chemo-immunotherapy from three possible regimens, but of note, 75% received R-CHOP. All patients had fulfilled the criteria for treatment and 80% had FLIPI intermediate or high-risk features. Responding patients were randomized to receive no further therapy or to receive 12 doses (every 8 weeks) for 2 years.

Patients who received rituximab maintenance therapy had significantly better rates of 3-year PFS than did those who received observation (75% vs. 58%), and the benefit to maintenance was observed in all FLIPI groups. Time to next treatment was also longer in the maintenance group than in the observation group. There were increased toxicities in the maintenance group, with most being infections, but these were largely self-limiting.

The type II glycoengineered anti-CD20 monoclonal antibody obinutuzumab is approved for use in combination with chemotherapy for first line treatment of advanced disease and then alone as maintenance therapy. The Gallium study enrolled 1202 patients with advanced (stage III/IV or stage II bulky) FL who required treatment according to GELF criteria.[59] Patients were randomized to receive either rituximab- or obinutuzumab-based frontline therapy. The chemotherapy consisted either of CHOP, CVP, or bendamustine and was allocated by the treating study center (NCT01332968). Obinutuzumab-chemotherapy improved 3-year progression free survival (PFS) when compared to rituximab-chemotherapy (80% vs. 73.3%) but with higher rates of treatment-related toxicity and no improvement in OS. In this cohort, patients with *EZH2* mutant FL appeared to benefit more from CHOP/CVP, whereas patients without *EZH2* mutations had longer PFS with bendamustine based regimes, regardless of whether chemotherapy was combined with rituximab or obinutuzumab.[60] This observation requires prospective validation but demonstrates that genomic biomarkers could be used to stratify patient treatment.

Conjugated Radio-Labeled Monoclonal Antibody Therapy

Complexing a radioisotope to a monoclonal antibody (radio-immunoconjugate) might be expected to improve efficacy over antibody therapy alone. Tositumomab complexes[127] Iodine to the anti-B1 antibody and has been studied extensively in the treatment of heavily pretreated,[128] untreated,[129] and for retreatment of indolent lymphomas.[130] The best responses are seen in previously untreated patients, with FL treated in a single treatment course with tositumomab in cases where there was a 95% OR, 75% CR, and 80% of assessable patients achieved eradication of PCR detectable MRD patients.[129] Median PFS was 6.1 years, with 40 patients remaining in remission for 4.3 to 7.7 years and no cases of myelodysplastic syndrome were observed. A SWOG study investigated chemo-immunotherapy with six cycles of CHOP chemotherapy followed 4 to 8 weeks later by tositumomab in 90 patients with previously untreated, advanced-stage FL.[131] The OR was 91%, including 69% CR and at median follow-up time of 5.1 years, the estimated 5-year OS was 87%, and PFS 67%, 23% better than CHOP alone on previous SWOG protocols. Ibritumomab Tiuxetan is a ^{90}Y-labeled anti-CD20 antibody and produced OR of 74% and 15% CR in 57 FL patients refractory to rituximab.[132] Toxicity is primarily hematologic, with nadir counts occurring at 7 to 9 weeks and lasting approximately 1 to 4 weeks. The risk of hematologic toxicity increased with dose delivered and with degree of baseline BM lymphoma involvement.[127] An acceptable safety profile was observed in relapsed patients with less than 25% lymphoma marrow involvement, adequate marrow reserve, platelets greater than 100,000 cells/μL, and neutrophils greater than 1500 cells/μL.

High-Dose Therapy as Consolidation of First Remission

The role of high-dose therapy and ASCT in patients with FL during first remission was explored in phase II trials,[133,134] and in three phase III randomized trials.[135–137] The GLSG trial[137] recruited 307 previously untreated patients up to 60 years of age and patients who responded after induction chemotherapy with two cycles of CHOP or mitoxantrone-chlorambucil-prednisone (MCP) and were randomized to ASCT or IFN-α maintenance. Among 240 evaluable patients, the 5-year PFS was 64.7% for ASCT, and 33.3% in the IFN-α arm ($P < .0001$). Acute toxicity was higher in the ASCT group, but early mortality was below 2.5% in both study arms. Longer follow-up is necessary to determine the effect of ASCT on OS. In the Groupe Ouest-Est des Leucémies Aigües et des Maladies du Sang study, 172 patients newly diagnosed with advanced FL were randomized either to cyclophosphamide, doxorubicin, teniposide, prednisone (CHVP), and IFN-α or to high-dose therapy followed by purged ASCT.[136] Patients treated with high-dose therapy had a higher response rate than patients who received chemotherapy and IFN-α (81% vs. 69%, $P = .045$) and a longer median PFS (not reached vs. 45 months), but this did not translate into a better OS because of an excess of secondary malignancies after transplantation. A subgroup of patients with a significantly higher event-free survival rate ASCT could be identified using the FLIPI. The GELF94 study enrolled 401 previously untreated patients with advanced-stage FL who were randomized to receive CHVP plus IFN-α compared with four courses of CHOP followed by HDT with total body irradiation (TBI) and ASCT and OR rates were similar in both groups (79% and 78% respectively) and 87% of eligible patients underwent ASCT. Intent-to-treat analysis after a median follow up of 7.5 years showed no difference between the two arms for OS ($P = .53$) or PFS ($P = .11$). Long-term follow up demonstrated no statistically significant benefit in favor of first-line ASCT in patients with FL, which the investigators conclude, should be reserved for relapsed patients. A meta-analysis concluded that high-dose therapy and ASCT does not improve OS in FL in first remission.[138] In view of these results, ASCT should be used in first remission only in the setting of clinical trials.

TREATMENT OF RELAPSED FOLLICULAR LYMPHOMA

Relapsed asymptomatic disease is not necessarily an indication for treatment and patients can again be managed expectantly. A number of factors must be taken into account in planning therapy and it is not possible to define treatment at relapse without considering the goal of therapy (palliative vs. potentially curative) performance status, previous therapy, response, and duration of response. In addition to the agents approved for use in first line disease, and which can be repeated if there has been a long duration of response, there are a number of agents approved for treatment after relapse (see Table 82.5). There is no consensus on the order or sequencing of specific agents, and relapsed patients should ideally be treated in clinical trials.

Single-agent rituximab is approved for relapsed lymphoma and is still widely used in this setting. A multicenter randomized trial in relapsed patients has demonstrated a survival advantage for chemoimmunotherapy with CHOP-R or CHOP followed by rituximab compared with CHOP alone, and a further benefit for rituximab maintenance therapy.[120] Agents approved for relapsed or refractory disease include the PI3 kinase inhibitors, idelalisib, duvalisib, copanlisib, the immunomodulatory agent, lenalidomide and the EZH2 inhibitor tazemetostat. CAR-T cells are also FDA approved for patients with relapsed or refractory FL after two or more lines of prior therapy.

In rituximab refractory cases or remissions of less than 6 months, obinutuzumab bendamustine therapy with obinutuzumab maintenance has been shown to improve PFS and OS when compared to bendamustine monotherapy.[139] Lenalidomide in combination with rituximab is superior to rituximab monotherapy in the relapsed setting and may be considered for those patients with short remissions after chemotherapy.[140]

For younger patients who are suitable candidates for either ASCT or reduced intensity conditioning (RIC) allogeneic transplantation, referral to a transplant center should be considered early to discuss the potential role and timing of transplantation. Best results are seen when transplantation is considered sufficiently early in the course of disease that patients have not already become chemo-refractory. High-dose therapy and ASCT remains an effective treatment approach for younger patients with chemo-responsive relapsed disease, SCT approaches must be considered in the context of the improving results that are being seen with novel salvage therapies.

Novel Agents

There are a large number of novel approaches that are being studied in patients with FL.

The phosphoinositide 3-kinase (PI3K) inhibitors idelalisib, copanlisib, and duvelisib, have shown efficacy in a relapsed setting,[141] and are approved for the treatment of relapsed FL. Given the dependence of FL on B cell receptor (BCR) signaling, monotherapy with ibrutinib, a Bruton tyrosine kinase inhibitor in the relapsed setting has only shown moderate efficacy, with an ORR of 38%.[142] Since a hallmark of FL is overexpression of BCL, this protein is also a logical target for small molecule inhibitors that can inhibit the antiapoptotic activity of BCL2. Venetoclax, a selective BCL2 inhibitor has proved disappointing in the relapsed-refractory setting, as a monotherapy and in combination with treatments active in FL.[143,144] Histone deacetylase (HDAC) inhibitors remove acetylation marks imposed by *CREBBP* and *EP300* and are showing promise as a means of overcoming the loss of function effect of these mutations. In a phase II study, pan-HDAC inhibitor vorinostat demonstrated moderate efficacy in the relapsed refractory setting with an ORR of 49%.[145,146] EZH2 inhibition with the oral selective small molecule, tazemetostat, shows ORR of 69% in *EZH2*-mutated patients and 35% in *EZH2*-wild type patients[147] and has recently been FDA approved for the treatment of relapsed refractory FL.

Therapies Targeting the Tumour Microenvironment

FL cells are critically reliant on interaction with components of the immune microenvironment for growth and survival. For many years it has been evident that FL is sensitive to treatment strategies that harness the immune system, from monoclonal antibodies, such as rituximab, to hematopoietic SCT. There are now a number of established and emerging treatments that impact both the TME and the tumour cells. The oral immunomodulatory drug lenalidomide augments anti-tumor immunity via mechanisms including enhanced immune synapse formation with T and NK cells and stimulating proliferation and activation of NK cells, enhancing NK mediated cytotoxicity.[148] Immune checkpoint inhibitors (ICI) that target programmed death-1 (PD-1) such as nivolumab, are effective in classic Hodgkin lymphoma, which displays frequent copy-number gains of the chromosomal region 9p24.1, encoding programmed death-ligand 1 (PD-L1) and PD-L2.[149] There is a rich infiltrate of PD-1 expressing T cells in the FL TME. Despite this, a phase II study evaluating the use of nivolumab monotherapy in relapsed refractory FL demonstrated very limited activity, with a 4% ORR. Responders had significantly higher proportions of CD3+ T cells in the TME than non-responders, however no significant differences in PD-1 or PD-L1 expression were observed.[150] A range of predictive biomarkers of response and resistance to ICI in solid tumors have been identified, such as mutation burden and intra-tumoral T cell infiltration, however these require investigation and validation in FL.[151]

Other cells within the TME are also the target of novel therapies. Phagocytic cells including macrophages and dendritic cells express signal regulatory protein alpha (SIRPα). The CD47-SIRPα interaction provides a macrophage immune checkpoint pathway, resulting in inhibition of phagocytosis. Hu5F9-G4, a humanized monoclonal antibody against CD47, targets the inhibitory effects on macrophage phagocytosis, enhancing antibody dependent cellular phagocytosis.[152] Hu5F9-G4 in combination with rituximab induced an ORR of 71% and a CR of 43% in patients with relapsed refractory FL.[153]Another emerging group are the CD20-CD3 bispecific antibodies, that target tumor B-cells and engage T-cells, directing antigen-specific T cell–mediated cytotoxicity to the malignant cells. One such agent, mosunetuzumab, has demonstrated activity in relapsed refractory FL with an ORR of 68% in a phase I clinical trial, NCT 02500407.[154]

There are numerous other agents in this class being explored for use in the relapsed refractory setting.[155,156]

The Role of Transplant in Relapsed Indolent Lymphomas

Unlike aggressive lymphomas, the use of high-dose chemotherapy with ASCT in the treatment of FL has not yet been fully established. The rationale for considering transplantation is that the disease is incurable using standard approaches, young patients with FL will die of their disease, and promising results have been observed in a number of phase II studies.[157–159] Detection of MRD has been a useful surrogate marker for tracking long-term PFS in patients examining the autologous stem cells or serial samples after transplantation.[159–163] A major concern relates to the risk of development of secondary myelodysplasia/acute myeloid leukemia.[164] The European Bone Marrow Transplant Registry (EBMTR) sponsored CUP (conventional chemotherapy, unpurged, purged autograft) study is the only prospective randomized trial to assess the role of ASCT in patients with relapsed FL.[165] The results of the study suggest a PFS and OS advantage of ASCT over conventional chemotherapy, with 4-year OS of 46% for the chemotherapy arm, versus 71% for the unpurged and 77% for the purged ASCT arms. The study was closed early because of slow accrual with 140 of the planned 250 patients accrued and only 89 randomized.

Allogeneic Bone Marrow Transplant

There is a trend towards increasing use of allogeneic SCT (allo-SCT) in the management of indolent lymphomas. In a report of the International Bone Marrow Transplant Registry (IBMTR), results after SCT are described for 904 patients with FL.[166] Among these patients, 176 patients underwent allo-SCT, 131 patients underwent ASCT using purged stem cells and 597 using purged autologous stem cells. The treatment related mortality (TRM) in these three groups was 30%, 14% and 8% respectively. Disease recurrence occurred in 21%, 43%, and 58% and 5-year OS was 51%, 62%, and 55%, respectively. The use of TBI containing regimens was associated with increased TRM but decreased risk of relapse. The use of aSCT was associated with increased TRM but with significantly lower risk of disease recurrence in keeping with a graft versus lymphoma effect in this disease. Trends suggest that outcomes are improving, and this is highly likely to continue with the increased use of RIC regimens that have become used increasingly since the time this registry data was collated. Long-term PFS has been observed after aSCT even in patients with refractory FL.[167] In 29 patients with FL, 11 of whom had refractory disease, the nonrelapse mortality was 24% and there was a 23% incidence of relapse. The 5-year OS was 58% with 53% event-free survival. A group of patients with very poor outcome are those patients who have relapsed after previous ASCT. The outcome following myeloablative aSCT of 114 such patients has been reported from the IBMTR.[168] The TRM was 22% and the probability of disease progression was 52% at 3 years. The use of TBI conditioning regimens and achievement of CR at the time of aSCT were associated with improved outcome. The use of RIC regimens appears to be associated with improved outcome. In 20 such patients, there was only one TRM from fungal infection and the 3-year PFS was an excellent 95%.[169] The outcome following RIC transplant regimen incorporating alemtuzumab immunosuppressive therapy has been reported for 81 patients with lymphoma and included 41 with low-grade, 37 with high/intermediate-grade and 10 patients with MCL, 31 of whom had relapsed following previous ASCT.[170] Patients received a conditioning regimen consisting of alemtuzumab, fludarabine, and melphalan, and received short course cyclosporin as graft-versus-host disease (GVHD) prophylaxis. The use of this conditioning regimen was associated with a low incidence of GVHD and the TRM was decreased in patients with low-grade compared with higher grade histology. The 3-year PFS was 65% for patients with low-grade lymphoma, 50% for patients with MCL and 34% for high-grade lymphoma ($P = .002$). Donor lymphocyte infusion (DLI) was given to 36 patients, 21 for relapsed or persistent disease and 15 for persistence of mixed chimerism. The use of DLI to treat relapse after aSCT is solely dependent upon the existence of a graft versus lymphoma effect. In seven patients with FL and small lymphocytic lymphoma who had relapsed after prior aSCT, six patients responded and four maintained CR for 43 to 89 months. The effectiveness of DLI to treat relapse after aSCT provides very strong evidence for a graft versus lymphoma effect that can be exploited in indolent lymphomas.[170,171] The role of RIC aSCT has been evaluated by Cancer and Leukemia Group B in a phase II study to evaluate the safety and efficacy in patients with recurrent low-grade B-cell malignancies, including 16 patients with FL.[172] The 3-year TRM was 9% and the 3-year OS was 81%. The incidence of grade II–IV acute GVHD was 29%, and extensive chronic GVHD was 18%.

CAR-T Cells

Axicabtagene ciloleucel (axi-cel), an autologous anti-CD19 CAR-T-cell therapy, has demonstrated clinically meaningful responses among patients with relapsed/refractory FL in the pivotal single-arm ZUMA-5, a non-comparative phase II trial (NCT03105336) and this resulted the FDA granting accelerated approval for axi-cell for FL after two or more prior lines of therapy.[173] ZUMA-5 demonstrated a 95% objective response rate, 79% complete response, OS, and at a median follow up of 23 months the median PFS was not reached. Like other single-arm trials, this does not provide comparative measures with other available treatments. To contextualize the clinical benefit associated with axi-cel in relapsed refractory FL, the results were compared to an international, retrospective, observational cohort from leading clinical sites, named SCHOLAR-5.[174] For comparison of the ZUMA 5 and SCHOLAR 5 cohorts a propensity weighting score was used for the SCHOLAR 5 patient group to create an external comparator arm with similar clinical characteristics as the patients in ZUMA 5 and demonstrated a meaningful improvement in ORR, CR, PFS, and, importantly, OS for CAR-T treatment over standard of care offered to the patients in the weighted SCHOLAR 5 cohort. The SCHOLAR 5 data also highlighted the lack of international consensus on the treatment of FL, particularly in the relapsed and refractory setting. Tisagenlecleucel has been shown to have promising results in clinical trials and, is now approved for use in Europe a has been filed for approval in FL.[175] Lisocabtagene maraleucel is currently approved only for FL3B.[176]

CHAPTER 83

MARGINAL ZONE LYMPHOMAS (EXTRANODAL/MALT, SPLENIC, AND NODAL)

Samer Al Hadidi and Carlos A. Ramos

The term *marginal zone* refers to a histologic compartment located at the periphery of lymphoid follicles immediately outside their mantle zone.[1] The marginal zone is especially evident in the spleen, although identical areas have been observed in other lymphoid structures, including mesenteric lymph nodes and mucosa-associated lymphoid tissue (MALT) (Fig. 83.1).[2] Ordinarily, it is composed predominantly of B cells that are slightly larger than mantle zone lymphocytes and strongly positive for surface IgM, but weakly positive for IgD (in contrast to mantle zone cells, which are strongly positive for IgD).[3] Marginal zone B lymphocytes are thought to be involved in fast protective responses against pathogenic encapsulated bacteria that do not trigger classic T cell–dependent humoral immunity.[4] They are also assumed to be the physiologic counterpart of a group of indolent non-Hodgkin lymphomas (NHLs) that are currently referred to as *marginal zone lymphomas (MZLs)*.

Although MZLs share a common denomination, arising from histologic similarities, new genetic findings and longer follow-up studies have established that the currently recognized subtypes of MZLs, initially described in the Revised European-American Lymphoma (REAL) classification, are different diseases.[5] In the most recent 2016 WHO classification of tumors of the hematopoietic and lymphoid tissues,[6,7] MZLs comprise three distinct entities: extranodal MZL (ENMZL) of MALT, or MALT lymphoma; splenic MZL (SMZL) with or without villous lymphocytes; and nodal MZL (NMZL) with or without monocytoid B cells. Immunoproliferative small intestinal disease (IPSID), also known as alpha heavy chain disease, Seligmann disease, or Mediterranean lymphoma, has been recognized as a variant of ENMZL.[8]

As in other hematological malignancies, a precursor state for MZLs has been recognized. Clonal B-cell lymphocytosis of marginal zone origin (CBL-MZ) is a condition where clonal B cells appear in the blood before the onset of overt MZL.[9,10] The circulating B cells have phenotypic features consistent with a marginal zone origin, but there is absence of clinical symptoms, splenomegaly, hepatomegaly, or lymphadenopathy. In a subset of patients (15% to 20%), CBL-MZ will progress to an overt MZL, most often SMZL.[9,10]

In aggregate, MZLs represent approximately 10% of all NHL.[11] Clinically, they behave indolently and have a prolonged course. Therefore, management strategies share similarity with other low-grade lymphomas,[12] although specific biologic characteristics and particular pathophysiologic mechanisms determine unique therapeutic approaches in some of the subtypes. This chapter will summarize the clinical characteristics and current management strategies for the different types of MZLs.

INITIAL EVALUATION OF MARGINAL ZONE LYMPHOMA

Adequate biopsy of a lymph node or a suspicious mass, obtained by endoscopic or conventional means, is preferred. A review by a hematopathologist with expertise in the field is essential to establish the diagnosis. In patients without easily accessible nodes or masses, computed tomography (CT) or ultrasound-guided core needle biopsy is usually well tolerated and may be adequate for diagnosis. Sufficient tissue must be obtained for proper histologic examination and required immunophenotypic and genetic studies. Hence, fine-needle aspiration (FNA) is not appropriate for diagnosis.

Physical examination with special attention to peripheral lymph nodes and the abdomen to look for splenomegaly should be performed. Initial laboratory evaluation should include a complete blood count with evaluation of a peripheral blood smear and basic biochemical studies, including lactate dehydrogenase (LDH) level, which is an important prognostic factor and a potential indicator of transformation from indolent to aggressive lymphoma. Antiglobulin tests and reticulocyte count may be useful to rule out autoimmune hemolytic anemia. Serum protein electrophoresis and immunofixation may demonstrate a monoclonal immunoglobulin. β_2-microglobulin levels may have prognostic value[13] as in other indolent lymphomas. Viral hepatitis (B and C) and human immunodeficiency virus (HIV) studies to exclude co-existing infections that affect therapeutic approaches should be obtained.

Depending on the primary site of disease, specific procedures may be indicated. Gastrointestinal MZLs may require repeat staging endoscopies, during which an adequate number of biopsies should be obtained. For gastric ENMZL, the most commonly affected site, the European Gastro-Intestinal Lymphoma Study (EGILS) group recommends a mapping procedure with a minimum of 10 biopsies taken from visible lesions and additional ones from macroscopically normal mucosa; the same procedure should be repeated to assess treatment response.[14–20] Since endoscopic biopsies are not transmural, endoscopic ultrasound (EUS) is a useful way to assess the depth of involvement, which has prognostic implications.[12–17] Moreover, EUS can be helpful to assess regional lymph node involvement. For head primaries, such as ocular adnexal ENMZL, appropriate directed examination and imaging studies (CT or magnetic resonance) are indicated. Routine endoscopy is suggested for patients with non-gastric MZLs, especially females with primary involvement of upper airways, salivary glands, or lungs, and in patients with high β_2-microglobulin levels or *Helicobacter pylori (H. pylori)* infection regardless of primary MZL site.[21,22]

STAGING OF MARGINAL ZONE LYMPHOMA

Imaging studies of the chest, abdomen, and pelvis, usually CT scans, should be obtained to adequately stage the disease. A positron emission tomography (PET) scan has been increasingly used for staging and evaluation of response to therapy in NHL, but it may be less useful in MZL because up to 60% of these lymphomas may be PET-negative, especially in early-stage gastric ENZML.[23] Some MZL series, however, document a PET-positivity rate of up to 80%,[24–28] with better detection rates seen for head and neck and bronchial versus gastric or ocular MZL.[29] The use of PET scan is particularly important in patients with possible transformation to high-grade pathology. Also for staging, and occasionally for diagnostic purposes, bone marrow aspirate (with morphology and flow cytometry) and biopsy are usually advocated, even in cases in which the likelihood of systemic disease is low, because any positive result has important implications for therapy. The European Society for Medical Oncology (ESMO) clinical practice guidelines for diagnosis of MZLs mandate bone marrow examination for NMZL and SMZL, while they highly recommend it in ENMZL, especially in the non-gastric type and when only local therapy is planned.[30]

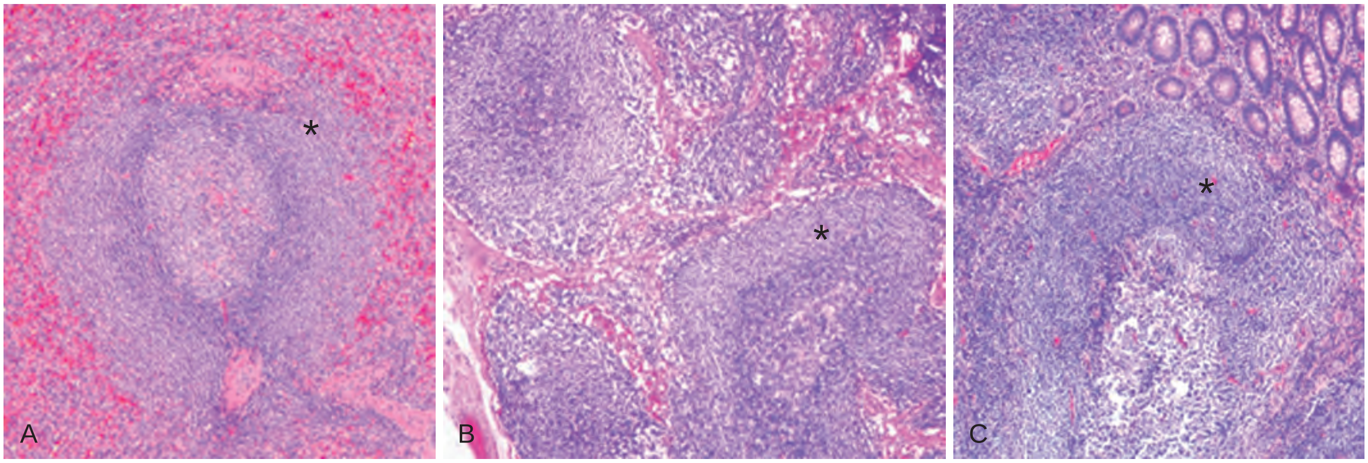

Figure 83.1 NORMAL MARGINAL ZONE CELLS. (A) Marginal zone cells are seen most readily in sections from the normal spleen. The splenic white pulp typically has three distinctive layers: the germinal center, the mantle zone, and external to this, the marginal zone (see *asterisk*). (B) Marginal zone cells are not usually seen in lymph nodes, but for some reason are sometimes present in mesenteric lymph nodes (see *asterisk*). They have a similar appearance to those in the spleen. (C) In the gastrointestinal tract, the lymphoid tissue in Peyer's patches is believed to have a marginal zone equivalent (see *asterisk*). The cells are again external to the mantle zone and are believed to traffic between the epithelium and the lymphoid follicle.

TABLE 83.1 **Staging Systems for Gastrointestinal Lymphomas**

Adapted Ann Arbor System[31]	Lugano System[32]	Paris System[33]	Areas Involved[a]
IE1	I_1	T1 N0 M0	Mucosa to submucosa
IE2	I_2	T2 N0 M0	To muscularis propria or subserosa
		T3 N0 M0	To serosa
	IIE	T4 N0 M0	To adjacent organs
IIE1	II_1	T1-4 N1 M0	Regional lymph nodes[b]
IIE2	II_2	T1-4 N2 M0	Non-regional abdominal lymph nodes
IIIE	IV	T1-4 N3 M0	Extra-abdominal lymph nodes
IV		T1-4 N0-3 M1	Distant organs
		B1	Bone marrow

[a] In case of more than one visible lesion synchronously originating in the gastrointestinal tract, select the characteristics of the more advanced lesion.
[b] Anatomic designation of lymph nodes as *regional* according to site: (1) stomach: perigastric nodes and those located along the ramifications of the celiac artery (i.e., left gastric artery, common hepatic artery, splenic artery); (2) duodenum: pancreaticoduodenal, pyloric, hepatic, and superior mesenteric nodes; (3) jejunum/ileum: mesenteric nodes and, for the terminal ileum only, the ileocolic as well as the posterior cecal nodes; (4) colorectum: pericolic and perirectal nodes and those located along the ileocolic, right, middle, and left colic, inferior mesenteric, superior rectal, and internal iliac arteries.

Staging of MZL is similar to that of other lymphomas; the Ann Arbor system, or an adapted version,[31] is used most frequently (Table 83.1). Nonetheless, specific staging systems have been adopted for particular sites. Gastrointestinal MZL is often staged according to a modified Ann Arbor scheme, commonly known as the Lugano staging system,[32] which incorporates indices corresponding to depth of mucosal invasion and proximity of affected lymph nodes to the primary lesion (see Table 83.1). Of note, the Lugano system has no stage III, and its stage IIE may refer to lesions that extend by contiguity to adjacent organs and not necessarily to secondary involvement of lymph nodes. Since the dissemination patterns of extranodal lymphomas are essentially different from those of primary nodal lymphomas, the EGILS group has proposed a new staging system (the Paris staging system)[33] that is based on the TNM scheme used for solid tumors (see Table 83.1). The International Society for Cutaneous Lymphomas (ISCL) and the cutaneous lymphoma task force of the European Organization of Research and Treatment of Cancer (EORTC) have also suggested a new, TNM-based staging system for cutaneous lymphomas other than mycosis fungoides and Sézary syndrome,[34] which may be used for the cutaneous forms of ENMZL (Table 83.2).

EXTRANODAL MARGINAL ZONE LYMPHOMA OF MUCOSA-ASSOCIATED LYMPHOID TISSUE TYPE

Epidemiology and Manifestations

ENMZL is the most frequent of the MZL subtypes, accounting for approximately 8% of all NHL and two-thirds of all MZLs.[11] An analysis of Surveillance, Epidemiology, and End Results (SEER) data quotes a yearly incidence rate of 1.59 per 100,000 adults in the United States.[35] The median age of presentation is around 60, with a wide range spanning from the third to the ninth decades, and there is a slight female predominance (55%).[36] In contrast to most other indolent lymphomas, ENMZL frequently presents at a localized stage (≈40% stage I and ≈30% stage II), and the risk for systemic dissemination is low (albeit variable depending on primary location), which has important implications for the choice of initial therapy.

The most commonly affected primary site is the mucosa of the gastrointestinal tract, in particular the stomach (approximately 44% of all ENMZL cases, with disease being usually multifocal) followed by the small intestine (≈7%). Ocular structures are also frequently involved (≈12%), namely the orbit (≈40% of all ocular adnexal ENMZL), the conjunctiva (35% to 40%), the lacrimal glands (10% to 15%), and the eyelids (≈10%).[37] Other commonly affected sites include the bronchial mucosa (≈11% of all ENMZL cases), the skin (≈9%), the salivary glands (≈6%), and the thyroid gland (≈6%). Sites that are more rarely reported include Waldeyer pharyngeal lymphoid ring, breast, liver, pancreas, urogenital tract, and central nervous system.[38–41] Findings at presentation depend on the specific organ affected. Gastric ENMZL may lead to dyspepsia, epigastric pain, nausea, anorexia, and manifestations of gastrointestinal bleeding.[42] Conjunctival ENMZL often forms a painless nodule or plaque that has a "salmon-pink patch" appearance and can be associated with erythema, chemosis, and foreign-body sensation.[43] Primary cutaneous

TABLE 83.2 International Society for Cutaneous Lymphoma/European Organization of Research and Treatment of Cancer Staging System for Cutaneous Lymphomas Other Than Mycosis Fungoides and Sézary Syndrome

Parameter[a]	Description
T	
T1	Solitary skin involvement
T1a	Lesion <5 cm diameter
T1b	Lesion >5 cm diameter
T2	Regional skin involvement: multiple lesions limited to 1 body region or 2 contiguous body regions[b]
T2a	All-disease-encompassing in a <15 cm diameter circular area
T2b	All-disease-encompassing in a >15 and <30 cm diameter circular area
T2c	All-disease-encompassing in a >30 cm diameter circular area
T3	Generalized skin involvement
T3a	Multiple lesions involving 2 noncontiguous body regions
T3b	Multiple lesions involving ≥3 body regions
N	
N0	No clinical or pathologic lymph node involvement
N1	Involvement of 1 peripheral lymph node region that drains an area of current or prior skin involvement
N2	Involvement of 2 or more peripheral lymph node regions or involvement of any lymph node region[c] that does not drain an area of current or prior skin involvement
N3	Involvement of central lymph nodes
M	
M0	No evidence of extracutaneous nonlymph node disease
M1	Extracutaneous nonlymph node disease present

[a] The ISCL/EORTC proposes to defer any stage groupings of the TNM classification until further information is available to validate specific stage grouping strategies.
[b] Definition of body regions: Head and neck: inferior border—superior border of clavicles, T1 spinous process. Chest: superior border—superior border of clavicles; inferior border—inferior margin of rib cage; lateral borders—midaxillary lines, glenohumeral joints (inclusive of axillae). Abdomen/genital: superior border—inferior margin of rib cage; inferior border—inguinal folds, anterior perineum; lateral borders—midaxillary lines. Upper back: superior border—T1 spinous process; inferior border—inferior margin of rib cage; lateral borders—midaxillary lines. Lower back/buttocks: superior border—inferior margin of rib cage; inferior border—inferior gluteal fold, anterior perineum (inclusive of perineum); lateral borders—midaxillary lines. Each upper arm: superior borders—glenohumeral joints (exclusive of axillae); inferior borders—ulnar/radial-humeral (elbow) joint. Each lower arm/hand: superior borders—ulnar/radial-humeral (elbow) joint. Each upper leg (thigh): superior borders—inguinal folds, inferior gluteal folds; inferior borders—mid-patellae, midpopliteal fossae. Each lower leg/foot: superior borders—mid-patellae, midpopliteal fossae.
[c] Definition of lymph node regions: Peripheral sites: antecubital, cervical, supraclavicular, axillary, inguinal-femoral, and popliteal. Central sites: mediastinal, pulmonary hilar, paraaortic, iliac.
From Kim YH, Willemze R, Pimpinelli N, et al. TNM classification system for primary cutaneous lymphomas other than mycosis fungoides and Sézary syndrome: a proposal of the International Society for Cutaneous Lymphomas (ISCL) and the Cutaneous Lymphoma Task Force of the European Organization of Research and Treatment of Cancer (EORTC). *Blood.* 2007;110(2):479–484.

ENMZL frequently presents as multiple red to violaceous papules, plaques, or nodules, most often on the trunk or extremities, in particular the arms, which very uncommonly ulcerate.[44] Salivary and lacrimal gland ENMZL is often preceded by sicca syndrome, with xerostomia or xerophthalmia. B symptoms are uncommon (≈15% of cases).[38] Bone marrow involvement has been reported in 2% to 20% of the cases and is usually more common in non-gastric ENMZL.[45]

IPSID usually affects young adults, with no gender predominance, and is seen most commonly in the Middle East and Northern Africa, usually in low socioeconomic status populations.[46] The disease affects the proximal small bowel diffusely and generally presents with a malabsorption syndrome, with steatorrhea, hypocalcemia, weight loss, abdominal pain, and fever. Cases involving the stomach, the colon, and very rarely the respiratory tract have been described.[8]

Pathobiology and Differential Diagnosis

Etiology

ENMZL is strongly associated with chronic antigenic stimulation, including that deriving from chronic bacterial infections[18,20,47–66] or autoimmune disorders[67–71] (Table 83.3), although the strength of this correlation for some primary disease sites is discordant among studies,

TABLE 83.3 Chronic Antigenic Stimulation and Extranodal Marginal Zone Lymphoma

	Bacterial Infections	
Organism	**Site**	**Prevalence (%)**
Helicobacter pylori[18,20,48–50]	Stomach	72–100
Campylobacter jejuni[51]	Intestine (IPSID)	≈70
Chlamydophila psittaci[52–62]	Conjunctiva	0–89
Borrelia burgdorferi[63–66]	Skin	0–42
Achromobacter xylosoxidans[273]	Lung	46

	Autoimmune Disorders	
Disease	**Site**	**Relative Risk**
Hashimoto thyroiditis[a][68,69]	Thyroid	67–80
Sjögren syndrome[67,70,71]	Salivary and lacrimal glands	6.6–30.6

[a] Estimated by assuming cases of thyroid histiocytic lymphoma were ENMZL because these were published before the REAL classification.

suggesting a possible geographic variation.[72] The common assumption about this association is that continual immune stimulation by bacterial or self-antigens leads to expansion of lymphoid elements in the connective tissue adjacent to the epithelium involved, initially leading to a process of reactive lymphoid hyperplasia. Persistent lymphocytic activation and proliferation predisposes to the accumulation of genetic errors that ultimately may result in antigen-independent growth and, consequently, lymphoma emergence.[73,74] The histologic distinction between the reactive inflammatory process associated with chronic infection (or autoimmunity) and lymphoma proper may be difficult, in which case demonstration of immunoglobulin gene monoclonality by molecular studies may aid in establishing the diagnosis of lymphoma.[75]

Histology

ENMZL is composed predominantly of morphologically heterogenous small B cells.[75] These resemble a spectrum spanning from small lymphocytes with scant cytoplasm to slightly larger cells with nuclei similar to those of centrocytes and having relatively abundant pale cytoplasm (leading possibly to a monocytoid appearance). These cells are located in the outer zone of reactive lymphoid follicles, extend into the interfollicular region, and may sometimes colonize the germinal centers. Larger, immunoblast- or centroblast-like cells may be present in small numbers, but an abundance of these should raise suspicion for diffuse large B-cell lymphoma (DLBCL), which requires different management. According to the most recent WHO classification, the term *high-grade MALT lymphoma*, denoting the presence of sheets of transformed cells, should not be used and instead these tumors should be diagnosed as DLBCL.

Often there are lymphoid infiltrates invading and destroying glandular structures, with eosinophilic degeneration of epithelial cells (so-called lymphoepithelioid lesions), which are strongly suggestive, albeit not pathognomonic, of progression to lymphoma in cases where the differential diagnosis with reactive lymphoid hyperplasia is in doubt (Fig. 83.2). Plasmacytic differentiation is frequent, especially in association with cutaneous, thyroid, and intestinal (IPSID) ENMZL and may pose differential diagnosis problems with lymphoplasmacytic lymphoma (LPL). These plasmacytoid cells often contain periodic acid–Schiff (PAS)–positive inclusions, known as Dutcher or Russell bodies, depending on whether they are located over the nucleus or in the cytoplasm, respectively.[76] Testing for MYD88 gene mutations, which are detected in the majority of LPLs but rarely found in MZLs, is helpful in these cases.[7]

In gastric ENMZL, histology also plays an important role in establishing the diagnosis of *H. pylori* infection. All biopsy samples should have sections appropriately stained for its detection (see Fig. 83.2D). Because proton pump inhibitors (PPIs) may decrease the sensitivity of detection, patients should stop taking these medications for at least 2 weeks before biopsies are obtained.[77,78]

Immunophenotype

ENMZL cells display common pan B-cell markers, such as CD19 and CD20. They are also usually positive for the complement receptors CD21 and CD35, antigens that are shared with follicular dendritic cells, and also for CD79a. Plasmacytoid cells can be CD138-positive. Helpful in the differential diagnosis with other indolent lymphomas, ENMZL are usually CD5-negative (in contrast to chronic lymphocytic leukemia/small lymphocytic lymphoma [CLL/SLL] and mantle cell lymphoma [MCL]), CD23-negative (in contrast to CLL/SLL), CD10-negative (in contrast to follicular lymphoma [FL]), and cyclin D1-negative (in contrast to MCL). They are also negative for BCL6, which may be helpful to exclude transformation to DLBCL. Except for IPSID, in which tumor cells express a truncated alpha heavy chain without any light chain, most ENMZL are typically positive for IgM or, less commonly, IgA or IgG, with light chain restriction. IgD expression is usually negative or very weak. These immunoglobulins may be secreted, especially when there is significant plasmacytic differentiation, and can give rise to a monoclonal band in the serum protein electrophoresis. The truncated heavy chains of IPSID usually do not appear as a monoclonal band because they co-migrate with other serum proteins but can be detected with anti-alpha heavy chain antibodies on immunofixation. ENMZL can be rarely associated with localized or systemic AL amyloidosis.[79]

Clinical practice guidelines published by ESMO propose that testing for CD20, CD5, CD10, and cyclin D1 by immunohistochemistry (IHC) is mandatory, whereas testing for CD23, IgD, and MYD88 mutation is suggested to aid in the diagnosis of MZLs.[30]

Genetics

Specific chromosomal aberrations have been associated with ENMZL, the frequency of which depends strongly on the primary site of disease (Table 83.4).[39,40,80] These abnormalities can be detected by conventional cytogenetics in metaphase plates or through fluorescent in situ hybridization (FISH) of interphase nuclei using specific

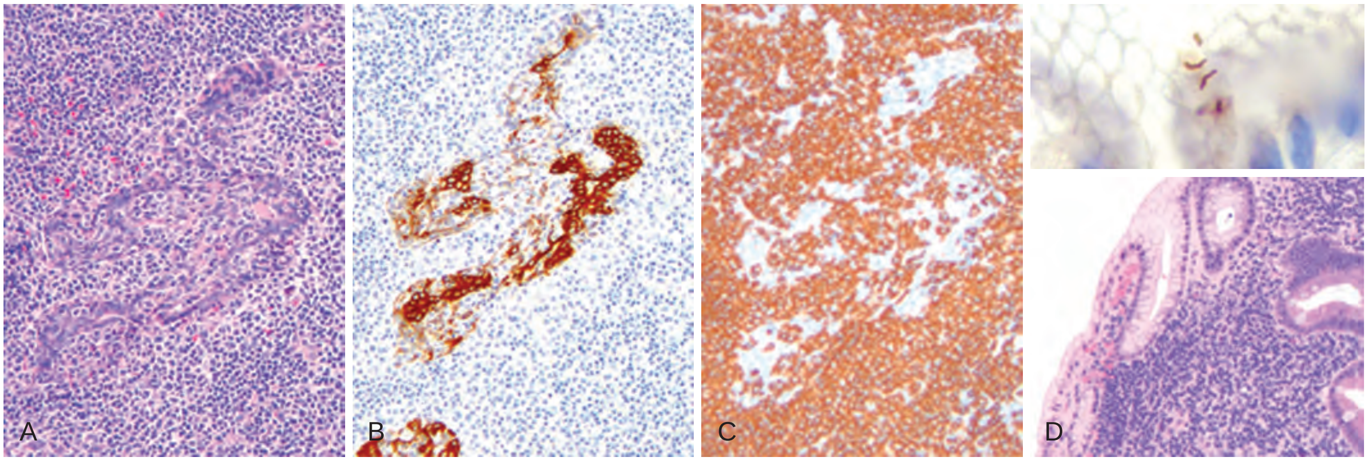

Figure 83.2 EXTRANODAL MARGINAL ZONE LYMPHOMAS OF MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT LYMPHOMAS). (A to C) An example of a MALT lymphoma in the parotid gland is illustrated with various stains. The glandular tissue is overrun by lymphoid cells, which disrupt and destroy the gland. The resulting structure is referred to as a *lymphoepithelial lesion* (A). These can be more clearly identified with a keratin stain (B) and with a B-cell stain such as CD20 (C), which illustrate the glandular remnant and the B-cell proliferation. (D) MALT lymphoma of the stomach is commonly associated with *H. pylori* infection, which can be identified by special stains *(top)*.

TABLE 83.4 **Frequency of Common Genetic Aberrations in Extranodal Marginal Zone Lymphoma According to Primary Site of Disease**

	Genetic Abnormality[39,40,80] and Genes Involved[89]					
	t(11;18)(q21;q21)	t(14;18)(q32;q21)	t(1;14)(p22;q32)	t(3;14)(p14.1;q32)	+3[a]	+18[a]

[a]Mostly partial trisomies. Data summarized based on references noted.

probes. The most commonly observed abnormality is the t(11;18)(q21;q21), which fuses the BIRC3 (baculoviral inhibitor of apoptosis repeat containing 3, also known as API2, or apoptosis inhibitor-2 protein) and MALT1 (MALT lymphoma translocation-1 protein) genes in chromosomes 11 and 18, respectively, leading to expression of a BIRC3-MALT1 chimeric protein.[81] The native MALT1 is part of a protein complex that includes the BCL10 protein (B-cell lymphoma protein 10) and that indirectly leads to nuclear factor κ-B (NFκB) activation, a process under strict control by several upstream factors. Expression of the fusion protein leads to constitutive activation of NFκB via canonical[82] and noncanonical[83] pathways, which in turn leads to resistance to apoptosis and uncontrolled proliferation. The t(11;18) has a special prognostic significance in gastric ENMZL, because its presence is associated with worse response to antibiotic therapy,[84] which is at least partly due to its higher prevalence in *H. pylori*–negative gastric ENMZL.[85]

Another, less frequently observed, abnormality is the t(14;18)(q32;q21). This translocation is different from that observed in follicular lymphoma, which involves the BCL2 gene, and instead brings the MALT1 gene under the influence of the immunoglobulin heavy chain gene promoter (IGH@), leading to overexpression of MALT1 and, through mechanisms akin to those of t(11;18), constitutive activation of NFκB. The t(1;14) (p22;q32) is seen even more rarely and causes overexpression of the BCL10 gene, which is placed under control of the IGH@ promoter, and, in turn, activation of the same pathways affected by MALT1. A fourth translocation, t(3;14)(p14.1;q32), described mostly in ocular, cutaneous, and thyroid ENMZL, involves the FOXP1 (forkhead box protein P1) transcription factor and the heavy chain promoter.[86] Although FOXP1 is overexpressed in these tumors, its exact significance in their biology is not fully understood.

Apart from the translocations described, all believed to be mutually exclusive, ENMZL has also been associated with gains of genetic material, in particular partial trisomies of chromosomes 3 (including regions affecting FOXP1, NFκBIZ [NFκB inhibitor zeta], and BCL6 [B-cell lymphoma protein 6]) and 18 (affecting NFATC1 [nuclear factor of activated T cells, cytoplasmic, calcineurin-dependent 1], and BCL2). Gains at 6p25 and losses at 6q (affecting TNFAIP3 [tumor necrosis factor, α-induced protein 3])[87,88] and 1p have also been reported.[89]

Consistent with a postgerminal center B-cell origin, ENMZL have rearranged immunoglobulin genes that display somatic hypermutation of their variable regions.[90] In the case of IPSID, there are deletions of the alpha heavy chain gene in the VH and CH1 regions, which result in the production of an abnormal heavy chain that cannot bind light chains to form a complete immunoglobulin molecule.[91]

Therapy for Early-Stage (I/II) Disease

Given its rarity, there are no randomized controlled trials defining the optimal treatment for ENMZL. Often, MZL patients are included in trials that enroll multiple types of indolent NHL. Most recommendations arise from consensus panels based on data from retrospective or uncontrolled prospective trials. The most extensive body of data has been gathered on gastric ENMZL.

Gastric Extranodal Marginal Zone Lymphoma

This form of ENMZL has a strong association with active *H. pylori* infection. If histologic analysis of the gastric biopsies obtained during staging endoscopy fails to demonstrate *H. pylori*, noninvasive methods, such as breath tests, stool antigen test, or serology, should be used to exclude the infection. Although not necessarily a marker of active infection, the presence of antibodies against *H. pylori* in an individual not previously treated for this bacterium implicates it in the pathogenesis of the lymphoma.

All patients with gastric ENMZL should be given *H. pylori* eradication therapy regardless of stage.[30] The focus of therapy for *H. pylori*–positive disease is on eradication of the infection with one of the currently recommended regimens for this purpose according to local antibiotic resistance pattern. These commonly combine a 4-week therapy course of a PPI and a 2-week therapy course of clarithromycin plus a second antibiotic, usually amoxicillin or metronidazole (triple therapy). However, this is an issue in flux as resistance to clarithromycin is increasing in several regions.[92] Alternatively, quadruple therapy with a PPI, bismuth, tetracycline, and metronidazole can be used. Eradication of *H. pylori* should be confirmed with an appropriate test, such as the urea breath test, at least 4 to 6 weeks after finishing antibiotherapy and 2 weeks after discontinuing PPI.[30,92] Pooled data from several prospective and retrospective studies suggest more than 90% eradication rates after initial antibiotherapy.[93] Persistent infection should be treated with a different course of antibiotics, preferably guided by sensitivity tests, because the same data suggests an eradication rate close to 100% after second- or third-line treatments. Repeat endoscopy with biopsies should be obtained 3 months after completion of antibacterial therapy in order to assess tumor response and also to allow histologic confirmation of *H. pylori* eradication. If *H. pylori* is still detected, a different antibiotic combination should be tried and the patient reassessed as above.[12,14]

Responses to therapy are classified according to biopsy findings on endoscopy. Complete histologic response (complete remission [CR]) should be confirmed by a second endoscopy 3 months later and is managed by observation and regular follow-up thereafter as clinically indicated. The presence of small residual lymphoid aggregates early after *H. pylori* eradication, corresponding to a category of *probable minimal residual disease* in the French Study Group of Adult Lymphomas (GELA) grading system for posttreatment evaluation, should also be managed as CR.[94] In some cases, these lymphoid aggregates have been shown to harbor cells with the same monoclonal rearrangements of the original tumor.[95] Nevertheless, these patients do not seem to have an increased risk for relapse and most will have evidence of complete response in a subsequent evaluation.[96]

Patients with overt residual (partial remission [PR]) or stable disease, as long as asymptomatic, can also be managed conservatively, with observation or antibiotherapy as appropriate, for several months. Of interest, responses may occur as late as more than 18 months after completion of antibiotic therapy.[50,96] If a patient achieves clinical and endoscopic remission after eradication of *H. pylori* but continues to have persistent microscopic disease on histology, waiting at least 12 months before starting another treatment is reasonable.[14,30] Progressive or symptomatic disease should be managed with local therapy, with radiotherapy being preferred. Despite its established efficacy in disease control, gastrectomy, because of its immediate morbidity and long-term metabolic complications, is currently reserved for management of rare complications such as perforation or bleeding that cannot be controlled endoscopically.[12,14]

A meta-analysis of 1436 patients with early stage (IE-IIE1) *H. pylori*–positive disease on prospective or retrospective studies estimates a CR rate of 78% after eradication of *H. pylori*,[97] but with individual study remission rates anywhere from 47% to 100%.[18,20,48–50,95,98–122] On univariate analysis of available data from the same studies, adverse risk factors for achieving remission included the presence of t(11;18), stage greater than IE1, proximal (body or fundus) location of lesions, and Western (versus Asian) residence. No good evidence is available to support adjuvant chemotherapy after anti–*H. pylori* treatment as a means to prevent recurrence in localized gastric MALT lymphomas, although this has only been formally addressed with an additional single agent (chlorambucil).[123]

The management of early-stage *H. pylori*–negative disease is controversial, with some groups suggesting involved field radiation therapy or, if radiation therapy is contraindicated, systemic therapy with rituximab as initial treatment,[12] whereas others propose a trial of anti-*Helicobacter* therapy.[14,124] The rationale for the latter derives from anecdotal reports of CR in *H. pylori*–negative gastric ENMZL patients that were treated exclusively with antibiotherapy,[125] with a meta-analysis suggesting a response rate of up to 19%.[126] These patients are assumed to have been infected with *H. pylori* that was missed by diagnostic tests or with a different species of *Helicobacter*, several of which have been recognized.[127,128]

Response to involved field radiation therapy (IFRT) is excellent, with some series reporting CR rates of up to 100% with total doses as low as 24 to 30 Gy given over 3 to 4 weeks to the stomach and perigastric nodes.[129–133] Radiation therapy in early-stage gastric ENMZL has not been associated with increased risk of cardiac death.[134] The lower dose of radiation (24 Gy) was shown to be safe and effective in a phase 3 clinical trial of indolent NHL, including ENMZL.[135] Recurrence rate is very low in these patients, but follow-up is limited for most series reported. International Lymphoma Radiation Oncology Group (ILROG) guidelines provide different volumes of radiation to be used for treatment of each site of ENMZL, with newer definitions of involved-site radiotherapy (ISRT).[136]

The optimal follow-up schedule is unknown, although most recommend periodic endoscopies every 3 to 6 months for the first 5 years and yearly thereafter.[12,14] Long-term follow-up data in patients with complete remission after *H. pylori* eradication document a 7.2% relapse rate overall (2.2% per year).[97] Some of these relapses were associated with *H. pylori* recurrence, and responses to retreatment for *H. pylori* were seen. Whether most complete remissions equate to cures is a question that will require longer follow-up studies. An additional argument in favor of periodic endoscopies is that *H. pylori* may be associated with an increased risk for gastric adenocarcinoma.[137]

Molecular studies should not be done routinely in follow-up biopsy samples, outside of a research protocol. Several studies have shown that molecular disease, defined by the presence of residual t(11;18) or monoclonal immunoglobulin as evidenced by polymerase chain reaction (PCR) methods, may still be detected even with complete pathologic remissions.[109,138,139] However, this finding is not associated with an increased relapse rate and thus is not currently helpful for clinical management.

Ocular Extranodal Marginal Zone Lymphoma

Localized forms of ocular adnexal ENMZL are most frequently managed with radiation therapy, with treatment specifics dependent on the exact location of the tumor in the orbit. Reported responses are excellent, with CR rates of 83% to 100%.[140–149] Local recurrence rates vary between 0% and 17%, and distant recurrences can occur in up to 25% over 10 years, although disease-specific survival approaches 100% in most series. The exact site of presentation correlates with the risk for systemic recurrence, the lowest being for conjunctival and the highest for eyelid primaries.[37] Long-term complications related to the use and the dose of radiation therapy, such as cataract formation and xerophthalmia, occur in approximately half the patients.[150] Lower-dose fractionated radiation (4 Gy in two fractions) is associated with 5-year progression-free survival (PFS) of approximately 70% and can be considered in some patients to avoid long-term complications.[151] The fractionation of lower-dose radiotherapy in ocular ENMZL was associated with lower risk of cataract and high durable response rates (96% at 2 years).[152] Despite the growing evidence of the efficacy of lower doses of radiation, the standard recommended dose remains 24 Gy in most patients.[30]

Based on the success of antibiotherapy for *H. pylori*–associated ENMZL and reports of the presence of *Chlamydophila psittaci* (by PCR, immunofluorescence, or electron microscopy) in ocular tissues of patients affected by ocular adnexal ENMZL, a course of an antichlamydial antibiotic has been evaluated as initial management for these patients.[52–62] Some studies have reported PR or CR in a significant fraction of these patients, with a prospective study documenting an overall response rate (ORR) of 65% and suggesting improved response rate and PFS in patients in whom *C. psittaci* eradication was documented.[57] However, the recommendation to treat with a tetracycline at initial diagnosis is controversial because the reported rates of association with *C. psittaci* are highly variable—some studies suggest prevalence as high as 80%, whereas others are not able to detect the organism in any of the patients. A meta-analysis has suggested that the benefit of antibiotherapy may be restricted to specific geographic areas and, even then, is likely to be limited.[153]

A recent phase 2 study using intralesional rituximab in 20 patients who received previous therapy for ocular ENMZL showed ORR of 65% with a median follow up of 3.5 years.[154] Intralesional rituximab was well-tolerated and can be considered in patients with ocular ENMZL who relapse or are refractory to initial therapy.

Cutaneous Extranodal Marginal Zone Lymphoma

Results for both surgical excision and radiation therapy for limited disease are comparable, with CR rates approaching 100%. Both approaches have a relapse rate (usually limited to the skin) of around 45%. Encouraging results have also been obtained with intralesional injection of rituximab or α-interferon.[44]

Studies from Europe have suggested an association between *Borrelia burgdorferi* infection and ENMZL of the skin, although this has not been reproduced in Asian and American studies.[63–66] In view of this, similar to ocular ENMZL, it has been suggested that a course of a tetracycline may be a reasonable first approach, especially in locations where the association has been documented or when infection by *B. burgdorferi* is detected.

Immunoproliferative Small Intestinal Disease

Antibiotherapy (varying from single-agent tetracycline to triple-antibiotic therapy with ampicillin, metronidazole, and tetracycline, or an *H. pylori* regimen)[155–158] has long been recognized as being able to induce CR in early-stage disease. IPSID has been associated with chronic infection with *Campylobacter jejuni*.[51] Therefore treatment of early disease is directed at bacterial eradication. Historic rates of remission vary between 30% and 70%, depending on the study. Maximal responses may take more than 5 months of therapy, and relapses occur in a subset of patients.

Other Extranodal Marginal Zone Lymphoma

Early-stage ENMZL in other primary sites is managed in a similar way to ocular adnexal or cutaneous forms. When feasible, surgery can be potentially curative and often may be done with primary diagnostic intent. If full resection is achieved, these patients may be observed. Otherwise, for sites not amenable to surgery or if there is residual disease after surgical excision (i.e., positive margins), radiation therapy is the usual preferred approach. It is important to tailor the radiation amount and site to the clinical setting to avoid irradiation of wide areas of the body, which can potentially result in adverse events. For example, in thyroid ENMZL, the entire thyroid gland should be irradiated.[159] If radiation is contraindicated and the patient is asymptomatic, observation is an option. Otherwise, systemic therapy as for advanced stage, preferably one with minimal toxicity, is appropriate.[12,160]

Therapy for Advanced-Stage (III/IV) Disease

The data regarding management of advanced-stage disease are also limited, because most large treatment series with long-term follow-up aggregate all indolent lymphomas and include only a small fraction of patients with MZL among other more frequent histologies. Thus most treatment approaches have been modeled after those for FL (see Chapter 82), and indeed the most common recommendation is that advanced ENMZL be managed as advanced FL.[12] In any case, there is some suggestion that responses may be better, possibly because of a usually lower burden of disease. Eligible patients should be included whenever possible in clinical trials. It is important to consider that patients with indolent lymphomas, especially MZL, tend to relapse and may do so multiple times. Accordingly, sequencing treatment to avoid toxicity and preserve adequate organ function is necessary to achieve long survival time.[159]

As in other indolent lymphomas, extensive disease is likely incurable with current approaches, which together with a generally slow pace of progression means that systemic treatment is not always indicated. Since no benefit in survival has been demonstrated with early systemic treatment of asymptomatic disease, unless a treatable etiology has been identified, initial management of asymptomatic patients with expectant observation is acceptable. While on this watch-and-wait approach, patients should be reassessed approximately every 3 months with history, physical examination, complete blood counts, basic chemistry, and LDH. Any new symptoms or findings suggestive of transformation should be investigated with a repeat biopsy to rule it out. Routine repeat imaging studies are controversial and should be considered on a case-by-case basis.

Indications for initiating systemic treatment include symptomatic disease due to mass effect or effusion, risk for local compressive disease, bulky lymphadenopathy, symptomatic splenomegaly, B symptoms, cytopenias due to bone marrow involvement, or rapid disease progression. Although unlikely to contribute to regression of established advanced disease, treatment of an underlying infection associated with MZL (such as *H. pylori* for primary gastric ENMZL and *C. jejuni* for IPSID) is advisable in order to remove any inciting factor.[30] Otherwise, as already mentioned, the same treatment approaches used for FL (see Chapter 82) are usually followed for ENMZL. Nonetheless, a few studies specifically addressing MZL are worth reviewing here.

Single Agent Rituximab

Given its low toxicity, single-agent immunotherapy with rituximab has generated a lot of interest in the management of advanced disease. Several small phase 2 studies have reported ORRs of around 75%,[161–163] with up to 48% CR in patients without previous therapy. In one of the series, median time to treatment failure was 22 versus 12 months in chemotherapy-naive versus non-naive patients, respectively.[161] Rituximab has activity in t(11;18)–positive disease.[162] Maintenance rituximab is controversial, and no data are available to support its use in ENMZL. Previous studies failed to showed OS benefit of maintenance rituximab and accordingly it is not usually recommended.[30,164,165]

Alkylating Agents

Single-agent alkylators have been used in this setting. A study of 24 patients with gastric ENMZL (stages IE or IV) treated with daily oral chlorambucil or cyclophosphamide for 12 to 24 months showed a CR rate of 75%, with the remaining patients achieving PR.[166] Remissions were durable in approximately half of the patients after a median follow-up time of 45 months. Another study of 21 patients (stages I to IV) treated with continuous alkylating drugs documented a CR rate of 42% and 89% in t(11;18)–positive and t(11;18)–negative disease, respectively.[167] After a median follow-up of 7.5 years, CR was sustained in all patients with translocation-negative disease, but in only one patient with t(11;18).

The combination of rituximab and chlorambucil has produced an impressive 100% CR rate in 13 patients with t(11;18)–positive gastric ENMZL (stages I to IV).[168] No relapses were observed after a median follow-up of 24 months in this report but long-term data were not available. This combination has been studied in a randomized controlled trial versus each single agent in 393 patients not responding or not suitable for local therapy.[169,170] CR rate, and 5-year event-free and PFS were better with the combination, but 5-year overall survival (OS) was 90% in the whole population, without significant differences between the three arms.[171]

Responses to bendamustine (with or without rituximab) have been documented in patients with relapsed/refractory indolent lymphomas, a small fraction of which were ENMZL.[172,173] A retrospective series of 14 ENMZL patients reported 10 CR and 3 PR with the combination of bendamustine and rituximab.[174] MALT2008-01, a phase 2 study, reported excellent results in 60 patients treated with 4 cycles of bendamustine and rituximab, which resulted in 100% ORR and 98% CR/unconfirmed CR. The combination was active in patients with t(11;18) and most recently the results were sustained, with a median follow up of 7 years.[175,176]

Purine Analogues

The purine analogue cladribine has also been used as single-agent therapy in a series of 25 patients (stages I to IV), and CR was obtained in 84% of them. After a median follow-up time of 80 months, seven patients experienced disease relapse.[177] Of note, one of the patients treated developed a myelodysplastic syndrome immediately after the third infusion of the drug.[178] Another purine analogue, fludarabine, has been used in combination with rituximab to treat a series of 22 patients (stages I to IV).[179] At the end of treatment (three cycles, with some patients requiring six), 90% of patients achieved a CR. The PFS rate at 2 years in patients with gastric and extragastric ENMZL was 100% and 89%, respectively. Both purine analogues seem to have activity in t(11;18)–positive gastric ENMZL.

Other Agents

Other single chemotherapeutic agents whose use has been reported in ENMZL include oxaliplatin, bortezomib, and vorinostat. In a study of 16 patients (stages I to IV) treated with oxaliplatin, a CR rate of 56% with a median time to response of 4 months was observed.[180]

Other studies of patients with relapsed, multiply treated indolent lymphomas report encouraging responses to bortezomib (two cases with PR out of two patients)[181] and vorinostat (one CR and one PR out of nine patients).[182] The combination of lenalidomide with rituximab was found to be effective and safe in a phase 2 study that included previously untreated patients.[183] Long-term follow-up is not available; therefore, the role of these agents as first-line therapy has not been established.

Combination Chemotherapy

Combination chemotherapy regimens reported in ENMZL patients include CVP (cyclophosphamide, vincristine, and prednisone) followed by radiation therapy,[184] FM (fludarabine and mitoxantrone),[185] CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone) followed by CVP,[186] MCP (mitoxantrone, chlorambucil, and prednisone),[187] R-CHOP (rituximab, cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone), and R-CNOP (rituximab, cyclophosphamide, mitoxantrone [Novantrone], vincristine [Oncovin], and prednisone).[188] These regimens have mostly been used in patients who were believed to have more aggressive disease. CR rates vary from 61% to 100%, with relapse rates reaching up to 36% on long-term follow-up. Advanced/transformed IPSID has usually been treated with combination chemotherapy, such as CHOP.[8,189]

Radioimmunotherapy

Radioisotope-conjugated forms of anti-CD20 antibodies (ibritumomab and tositumomab) have also been used both as first-line[190] therapy (eight CRs and one PR in nine patients with ocular adnexal ENMZL) and for relapsed disease[191,192] (three CRs and three PRs in six patients with ocular adnexal ENMZL; four CRs and one PR in six patients with a variety of primary sites). The combination of conventional radiation therapy and rituximab has been studied for early-stage follicular lymphoma.[193] There are no published studies of its use on ENMZL.

Therapy for Relapsed Disease

Limited relapses can be retreated, if feasible, with local therapy. Otherwise, treatment considerations are similar to those described for advanced disease. Symptomatic, relapsed extensive disease will usually require an alternative regimen to those previously used.

Ibrutinib, a Bruton tyrosine kinase (BTK) inhibitor, is Food and Drug Administration (FDA) approved for use in MZL patients who received at least one prior therapy containing rituximab. An updated analysis of a phase 2 study that used ibrutinib (560 mg daily) in 63 patients reported ORR of 58% and CR of 10% with a median follow-up of 33 months. The median duration of response was 27.6 months with a median PFS of 15.7 months. ORR was similar in ENMZL (63%) and splenic MZL (62%) and slightly lower in nodal MZL (47%).[194,195] The most common grade 3 adverse event was anemia (16%).

The combination of lenalidomide and rituximab is approved for the treatment of adult patients with previously treated marginal zone lymphoma based on results of two trials. One of these trials (AUGMENT) showed ORR of 65% (20/31 patients) with rituximab and lenalidomide versus 44% (14/32 patients) with rituximab alone in MZL patients.[196]

The phosphoinositide 3-kinase (PI3K) inhibitor copanlisib has demonstrated significant efficacy, with ORR of 70% in 23 patients with MZL, although most responses were partial.[197] The combination of copanlisib with rituximab was found to be better than single-agent rituximab in the most recent CHRONOS-3 study, which studied multiple subtypes of indolent NHL.[198] Approximately 20% of the enrolled patients had MZL and their responses seem to be consistent with the overall group of treated patients, with median PFS of 21.5 months (copanlisib with rituximab) versus 13.8 months (rituximab). Copanlisib was associated with more frequent serious treatment-related adverse events including hyperglycemia, hypertension, and pneumonia.[198] Other PI3K inhibitors, such as duvelisib and idelalisib, may have similar activity. A dual PI3K and casein kinase 1 (CK1) inhibitor, umbralisib, was FDA approved specifically for use in MZL patients who received at least one prior therapy containing a CD20 monoclonal antibody.[199] but approval has been later withdrawn for safety concerns.

The role of hematopoietic stem cell transplantation is controversial because most series do not directly address ENMZL and thus most recommendations are again extrapolated from studies of FL.[200–204] Given that most young patients with relapsed systemic ENMZL are likely to succumb to complications of their disease, considering them for allogeneic stem cell transplantation is reasonable, although this should preferably take place on a clinical trial. Encouraging results have also been reported with high-dose therapy and autologous stem cell transplantation specifically for MZL.[205]

Prognosis

Overall, prognosis of limited-stage ENMZL is excellent, as mentioned in each of the treatment subsections. A recent long-term report of 487 patients with early-stage ENMZL showed excellent outcomes with 5-year OS of 89%, with a median follow-up of 4.7 years.[206] The 5-year relapse free survival was 60%. Even for advanced disease, the expected lymphoma-specific survival at 5 years is close to 90%, with some series showing survivals similar to those of early disease. A retrospective analysis of SEER data lists the best 5-year OS for cutaneous (88%), ocular (83%), and thyroid (85%) forms, and worst for genitourinary (76%), intestinal (69%), and central nervous system (71%) forms.[35] As in other indolent lymphomas, transformation to aggressive forms (DLBCL) can occur, but this is thought to be a rare event (less than 10% of cases) associated with acquisition of additional genetic abnormalities.[41] Regardless, even patients in CR after first-line therapy can develop DLBCL. Main predictors for transformation, which is associated with worse survival, were reported to include elevated LDH, more than 4 nodal sites at the time of MZL diagnosis, and failure to achieve CR after initial therapy.[207] For instance, 0.05% of individuals with gastric ENMZL who underwent successful antibiotic treatment had evidence of DLBCL between 6 months and 2 years after achieving remission.[97] There is a sixfold increased risk of gastric adenocarcinoma in patients with gastric MZL, however the risk is low at 2.4%.[208] On the other hand, untreated IPSID tends to evolve to large-cell transformation.[8,189]

As for other lymphomas, the International Prognostic Index (IPI)[209] (see Chapter 84) predicts outcomes, with reported 5-year OS of > 90%, 70% to 80%, and 40% to 50% for patients with low, low-intermediate/high-intermediate, and high-risk scores, respectively.[36] Nonetheless, the utility of the IPI in ENMZL has been disputed.[210] One of the main criticisms to its use in patients with indolent lymphomas is that prognostic subgroups do not have a good discriminating power, because most patients are assigned to the favorable outcome groups and only very few patients are allocated to the adverse prognostic groups.[211] To circumvent this issue, modifications of the original IPI have been proposed in some cases.[212] A new prognostic score, MALT-IPI, was developed based on data of 401 newly diagnosed patients and subsequently validated in a separate cohort of 633 patients.[213] Three factors were found to be of prognostic value: age ≥70 years, Lugano stage III or IV, and elevated LDH. High risk was defined as two or more risk factors and was associated with 5-year event-free survival of 29% and 5-year OS of 64%. The utility of MALT-IPI was consistent in gastric and non-gastric ENMZL, and also across different treatment groups, which include rituximab-containing regimens.

The recent explosion of genomic analysis of these neoplasms has also led to a plethora of findings that have been shown to have prognostic significance in ENMZL. For instance, the expression of FOXP1 in tumors predicts poor prognosis and transformation to diffuse large B-cell lymphoma.[214] Disruption of NFκB signaling was found to be correlated to clinical outcome and can be helpful as a biomarker.[194] CARD11 and KMT2D mutations were associated with worse PFS.[194] Although these findings are not yet incorporated into clinical practice, as they become more widely available, they may be useful for risk stratification and therapeutic decisions (see box on Suggested Treatment Approach to Extranodal Marginal Zone Lymphoma).

SUGGESTED TREATMENT APPROACH TO EXTRANODAL MARGINAL ZONE LYMPHOMA

Stage I/II

Gastric H. pylori–positive

- Antibiotic therapy
- Repeat endoscopy in 3–6 months
- If still *H. pylori*–positive and no progression, alternative antibiotic therapy
- Repeat endoscopy in 3 months

Nongastric, gastric H. pylori–negative or not responding to antibiotic therapy

- Antibiotic trial for gastric *H. pylori*-negative, even in advanced disease
- Antibiotic trial for stage I ocular, or cutaneous?
- Involved field radiation therapy (24–30 Gy)

Stage III/IV or relapsed after antibiotic and radiation therapy

- Expectant observation until indication to treat
- Single-agent rituximab
- Rituximab + bendamustine, chlorambucil, cyclophosphamide or lenalidomide
- Ibrutinib (in relapsed disease after prior use of rituximab)
- PI3K inhibitors

SPLENIC MARGINAL ZONE LYMPHOMA

Epidemiology and Manifestations

SMZL (Fig. 83.3) is a rare disease, corresponding to <1% of all NHLs,[11] with a yearly incidence rate of 0.25 per 100,000 adults in the US according to SEER data.[35] The median age at diagnosis is around 65, but as with ENMZL, the age range is wide and there may be a slight female predominance. The vast majority of patients present with advanced-stage disease involving the spleen (with splenomegaly in more than 80% of patients), abdominal (mainly splenic hilar) lymph nodes, and in 83% to 94% of patients, the bone marrow.[215–218] Peripheral lymphadenopathy is, however, uncommon. Liver involvement is seen in up to one-fourth of patients, and rarely other nonhematopoietic sites can also be involved. B symptoms occur in approximately 25% to 60% of patients, depending on the series.[216,217]

Circulating villous lymphocytes (with short polar villi) can be seen in approximately two-thirds of patients (see Fig. 83.3B) and frank lymphocytosis in up to one-half. This has led to a prior designation of *splenic lymphoma with villous lymphocytes* being given to a specific presentation of this disorder and explains why the disease was called *SMZL with or without villous lymphocytes*. CBL-MZ may precede the onset of SMZL.[10] Anemia is seen in about one-half to two-thirds and thrombocytopenia in one-fifth of cases, which can be the result of bone marrow involvement or an autoimmune process (seen in approximately 15% of patients). Between 25% and 40% of patients have a low-level circulating monoclonal immunoglobulin (mostly IgM),[217] and in a few patients, especially in those with active hepatitis C virus (HCV) infection, mixed cryoglobulins can be demonstrated, which can be associated with vasculitis.[219,220] Autoimmune manifestations occur in 20% of the patients, including cold agglutinin disease, acquired von Willebrand disease, autoimmune hemolytic anemia, and immune thrombocytopenia. Ultrasonography can help define focal splenic lesions and may help in the diagnosis.[221]

Pathobiology and Differential Diagnosis

Etiology

Approximately 10% to 20% of SMZL patients from European series have evidence of HCV infection,[215,218] and a significant fraction of these patients can achieve CR after successful treatment of the infection.[220,222] This raises the possibility that, like ENMZL, this disease is associated with chronic antigenic stimulation. However, no other infections have been described in clear connection to SMZL, despite a suggested association with *Plasmodium*,[223] and thus the etiology of most cases is unknown.

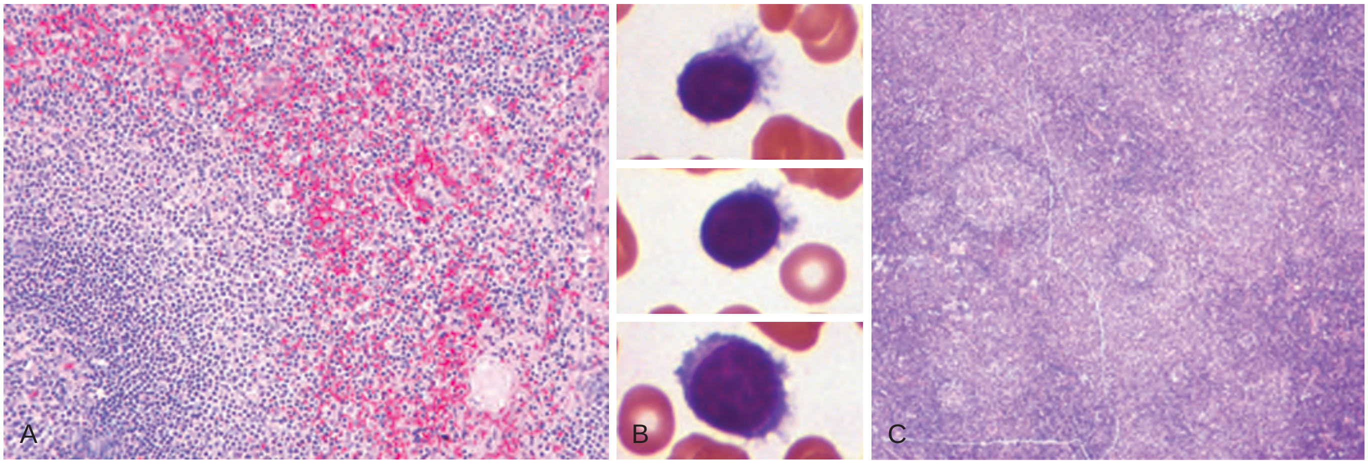

Figure 83.3 SPLENIC MARGINAL ZONE LYMPHOMA, VILLOUS LYMPHOCYTES, AND PRIMARY NODAL MARGINAL ZONE LYMPHOMA. (A) Splenic marginal zone lymphoma is characterized by an expansion of the marginal zone cells *(left)* and their spilling into the red pulp *(right)*. (B) These cells can also become leukemic and can be recognized on the peripheral blood smear. Note the polar distribution of the cytoplasmic projections. (C) Primary nodal marginal zone lymphoma is rare, and involvement of a node by extranodal disease must always be ruled out. NMZL is histologically characterized by an expansion of marginal zone cells (formerly referred to as monocytoid B cells) in between reactive germinal centers.

Histology

The classic histology of SMZL includes a population of small lymphocytes that surrounds or replaces the germinal centers of the lymphoid follicles of the white pulp, effacing their mantle zone, and progressively merging peripherally with larger, marginal zone–like cells.[224] These cells expand to the interfollicular zones and invariably invade the red pulp (see Fig. 83.3A). A few scattered lymphoblasts are usually present, and as in ENMZL, plasmacytic differentiation can occur. Bone marrow involvement usually gives rise to nodular interstitial lymphoid infiltrates that resemble the histology of the spleen, although the cell types are usually admixed, without distinct zones. Peripheral blood involvement is typically associated with lymphocytes that have short polar villi (Fig. 83.3B), as mentioned above, although the villi may be absent.

Immunophenotype

The phenotype of SMZL is similar to that of ENMZL (see earlier), but in contrast to the latter, SMZL is usually IgD-positive. The same differential diagnosis considerations apply; additionally, because this disease behaves as a chronic B-cell leukemia, it is of interest that SMZL is negative for annexin A1 and CD25 and usually negative for CD103 (in contrast to hairy cell leukemia).[224] Rare cases may be CD5-positive.[225]

Genetics

A substantial amount of genetic data on SMZL has been accumulated during the last decade. A review of 330 patients with SMZL documented del(7q) (affecting different loci in regions q21 to q36) as the most frequent cytogenetic abnormality (≈40% of patients).[218] Gains of genetic material from chromosomes 3 (≈25%), 8 (≈10%), and 12 (≈8%) were also seen frequently. Translocations involving 14q32, different from those seen in ENMZL, occurred in 12% of patients. The translocation t(11;18) was not seen in SMZL. More than 50% of cases had three or more cytogenetic aberrations. Deletions of 8p and 17p (TP53) have been seen in approximately 15% of cases analyzed with DNA microarrays.[89] The biologic significance of these chromosomal abnormalities is unclear.[226]

Approximately 50% to 60% of SMZL have evidence of somatic hypermutation of the immunoglobulin genes,[218,226–228] and there is some evidence that, similar to CLL, these cases may have better overall prognosis.[227] Both mutated and unmutated tumors display bias in variable region usage, with predominance of VH1-2 family genes. Intraclonal variation has also been described, which suggests the presence of ongoing mutational events in these lymphomas.[229]

Similar to hairy cell leukemia, the V600E BRAF variant has been reported in SMZL, but only in 16% of a small series of patients.[230,231] In addition, the L265P MYD88 mutation commonly observed in Waldenström macroglobulinemia/lymphoplasmacytic lymphoma is rare in SMZL.[232] These findings may help distinguish these disorders when the diagnosis is in doubt.

Therapy

Since SMZL behaves indolently, in asymptomatic patients without significant or progressive cytopenias, expectant observation is a reasonable approach. The 5-year OS rate of 32 patients with asymptomatic SMZL who never received treatment was 86% in one published series.[233] In another series, 10 out of 14 untreated patients were alive between 1 and 6 years after diagnosis.[234]

Indications for lymphoma treatment are similar to those for advanced-stage ENMZL, including symptomatic splenomegaly. As for other forms of MZL, there are no data from randomized trials guiding selection of therapy, and most recommendations come from consensus opinions of experts in the field.[12,30]

Anti-Hepatitis C Virus Therapy

In patients with evidence of active HCV infection, anti-HCV therapy is recommended. A study of the effects of interferon-α (IFNα) in SMZL showed eight complete and one partial hematologic responses in nine HCV-positive patients after clearance of HCV (with two of them requiring addition of ribavirin), versus no responses in six HCV-negative individuals.[222] One patient in CR treated initially only with IFNα had a relapse of the lymphoma with detectable levels of HCV RNA; treatment with IFNα and ribavirin resulted in second complete virologic and hematologic responses. Given that newer anti-HCV drugs are less toxic and more effective than IFNα, these may become first choice for these patients. Of note, evidence of monoclonal immunoglobulin gene rearrangement may persist after successful treatment of HCV and SMZL.[220]

Rituximab-Based Regimens

Rituximab has been used as single agent or in combination with chemotherapeutic drugs in symptomatic HCV-negative patients or in those whose disease did not respond to anti-HCV treatment. The response rate to single-agent rituximab in a retrospective subseries of 25 patients with splenic and nonsplenic MZL was 88%, which compared favorably with that of 11 patients who received chemotherapy alone (55%).[235] In two other retrospective studies, rituximab was found to be an effective therapy in 90% to 95% of patients with SMZL, with reduction in splenomegaly and improvement in blood counts.[236,237] Because of its low toxicity and improved survival outcomes, rituximab-containing regimens are often used as initial therapy for symptomatic SMZL.[238] Maintenance rituximab has a potential role in SMZL, with evidence of 64% improvement in 10-year progression free survival.[239] Rituximab may also be helpful in SMZL patients with autoimmune disorders such as autoimmune thrombocytopenia or autoimmune hemolytic anemia.

The combination of bendamustine and rituximab was investigated in a phase 2 study where 56 patients with newly diagnosed SMZL were given six cycles of therapy.[240] Outcomes were excellent with ORR of 91% and CR of 73% after a median follow up of 32 months.

Splenectomy

Before rituximab was widely available and studied in SMZL, splenectomy was frequently used as first-line therapy. A benefit of this procedure, which may be done for diagnostic purposes in patients with localized disease, is the usual improvement of cytopenias occurring as a result of hypersplenism. Precise response rates to splenectomy are difficult to ascertain. All of 25 patients in a series treated with splenectomy alone had responses, including 2 CRs.[13] Most responses were durable: only 8 of these 25 patients experienced disease progression on long-term follow-up, with a median time to progression of 32 months (with a range of 4 to 137 months).[241] Moreover, all of 16 patients treated with first-line splenectomy in an earlier series had good responses, most likely partial (complete responses could not be assessed because of a lack of bone marrow assessment after treatment); two patients progressed subsequently.[234] Finally, another series of 28 patients documented a 5-year OS of 71% after splenectomy; no CRs were reported.[233] Although an effective procedure with very low operative mortality, splenectomy is associated with a long-term increased risk of infection and sepsis, and possibly a hypercoagulable state with potential cardiovascular complications.[242,243] On the other hand, retrospective analysis of SEER data showed no advantage of splenectomy over other treatment approaches for SMZL.[244] Given these considerations, the role of therapeutic splenectomy in SMZL has been questioned.[245,246]

Ibrutinib

Ibrutinib is effective in MZLs including SMZL, with ORR of 62% and can be considered in patients who relapse after the use of rituximab.[194,195]

Chemotherapy

Single alkylating agents (chlorambucil or cyclophosphamide) have also been used for treatment of SMZL. Most series are very small, but all report a significant fraction of responses, albeit mostly partial. Fludarabine has produced encouraging results also,[247,248] but the efficacy of cladribine is controversial.[249,250] The use of combination chemotherapy (including CVP and CHOP) has also been reported, but differences between CHOP (or CHOP-like) therapy and other less-intensive regimens could not be demonstrated.[217] In a subseries of 19 patients treated with chemotherapy alone, the 5-year OS rate was 64%.[233]

Radiation Therapy

In patients ineligible for any of the aforementioned therapies, radiation therapy to the spleen can be used for symptomatic control. Even low-dose radiation (around 4 Gy) can result in resolution of splenomegaly and correction of cytopenias,[251] at least temporarily.

Although it is tempting to compare the results of observation, splenectomy, and systemic therapy, this is not prudent. All published series have considerable selection bias because patients who are believed to have more aggressive disease have been usually offered more-intensive therapies.

Prognosis

Reported 5-year OS rates vary from 65% to 78%,[217,233] with a median survival of more than 10 years.[13,252] The Italian Lymphoma Intergroup (ILI) has proposed a prognostic model using hemoglobin less than 12 g/dL, LDH higher than normal, and albumin less than 3.5 g/dL as risk factors.[215] Low-risk (no factors), intermediate-risk (1 factor), and high-risk (2 or more factors) patients have 5-year OS of 83%, 72%, and 56%, respectively. Shorter survival has been associated with CD38 expression, unmutated variable region immunoglobulin genes, and expression of a specific set of NFκB pathway genes (by gene expression array).[226] The presence of both del(8p) and del(17p) involving TP53 is associated with worse prognosis, although isolated deletion 17p is not.[89] An international retrospective survey conducted by the SMZL study group on 593 patients proposed a new prognostic model called HPLL (Hemoglobin level, Platelet count, LDH level, and extra-hilar Lymphadenopathy), which was subsequently simplified and validated.[253–255]

A recent SEER analysis reported no significant difference in SMZL outcomes by treatment strategy.[252] Transformation to aggressive lymphoma may occur in around 10% of cases (see box on Suggested Treatment Approach to Splenic Marginal Zone Lymphoma).[13]

SUGGESTED TREATMENT APPROACH TO SPLENIC MARGINAL ZONE LYMPHOMA

HCV-positive
- Anti-HCV therapy

HCV-negative (or not responding to anti-HCV therapy) or relapsed
- Expectant observation until indication to treat
- Single-agent rituximab
- Rituximab + bendamustine (or combination chemotherapy) ± maintenance rituximab.
- Ibrutinib (in relapsed disease after prior use of rituximab)
- Splenectomy (if other treatments fail)
- Splenic irradiation (if other treatments contraindicated)

NODAL MARGINAL ZONE LYMPHOMA

Epidemiology and Manifestations

NMZL represents approximately 2% of all NHLs, corresponding to a yearly incidence rate of 0.83 per 100,000 adults in the US according to SEER data. The reported incidence of NMZL has increased significantly over the previous decade,[35] but it is unclear whether this is the result of a true increase in the number of cases or of an increased recognition of this entity. The diagnosis requires the absence of extranodal or splenic disease, the presence of which makes ENMZL and SMZL more likely. The median age at presentation is around 60, and in most series, there is a slight female predominance. Most patients present with asymptomatic lymphadenopathy, most often in peripheral lymph nodes (especially cervical and inguinal), which is frequently associated with mediastinal or abdominal involvement. The percentage of B symptoms is extremely variable between different studies with most recent series reported in less than 20% of patients.[38,216,256–260] Except in three of the published series,[257–259] the majority of patients present with stage III or IV disease (approximately 70% to 80% of cases), with bone marrow involvement detected in up to two-thirds of cases. Anemia and thrombocytopenia have been described in up to 30% and 10% of cases, respectively. A monoclonal IgM is seen in approximately 10% of patients. A pediatric form, with excellent prognosis, has been recognized.[261]

Pathobiology and Differential Diagnosis

Etiology

As with SMZL, some series have reported an association with HCV in up to one-fourth of NMZL cases, but with a strong geographic variation (mostly Italian and Spanish series).[256,257,259,260,262] No other clear association has been described.

Histology and Immunophenotype

The histology and immunophenotype of NMZL resembles that of ENMZL or SMZL (see Fig. 83.3C).[263] The frequent presence of monocytoid B cells explains why this disease has been previously called *monocytoid B-cell lymphoma*[264] and *NMZL with or without monocytoid B cells*. A primary ENMZL should always be ruled out with appropriate studies (such as endoscopy) because 30% and 40% of cases presenting as NMZL may in fact represent nodal dissemination of an ENMZL of MALT type.[265,266]

Genetics

Complex genetic abnormalities are usually observed in NMZL, with the most frequent being partial trisomies of chromosomes 3 and 18, affecting the same regions as in ENMZL. None of the characteristic translocations of ENMZL are seen in NMZL, however.[89] Furthermore, del(7q) is also not observed. More than 75% of cases have mutated immunoglobulin genes.[257,267] Of interest, different VH immunoglobulin gene segments are predominantly involved in HCV-positive and HCV-negative patients, raising the possibility that distinct antigens drive different underlying chronic immune stimulation processes.[268] Recent gene sequencing work reported recurrent mutations in *KMT2D* (*MLL2*), *KLF2*, *PTTPRD*, and *NOTCH2*.[269]

Therapy

Few data are available to guide treatment of NMZL, and most recommendations are extrapolated from the management of FL.[12] As in other indolent lymphomas, expectant observation is appropriate for asymptomatic patients. A trial of anti-HCV can be considered in patients with HCV who do not require immediate treatment.[30] Radiation therapy may be curative for early disease. Symptomatic advanced disease can be managed with the same general approach described for advanced ENMZL, although there is usually a tendency to use combination chemoimmunotherapy identical to that for FL as first-line treatment because of the generally worse outcomes with NMZL as compared with ENMZL. Ibrutinib can be used in NMZL patients who relapse after use of rituximab; however, ORR was reported to be lower (47%) when compared to either ENMZL or SMZL (~63%).[194,195]

Prognosis

NMZL is usually associated with worse prognosis when compared with the other forms of MZL.[38] OS rates at 5 years vary from 55% to 70% in most series, except for those containing a greater proportion of early-stage disease, which report 5-year survivals of up to 80%. Five-year PFS is around 30%. Relapse in extranodal sites is rare. As in other lymphomas, the IPI correlates with outcomes, as does the Follicular Lymphoma International Prognostic Index (FLIPI)[270] (see Chapter 82). In a series of 47 patients, those with low-, intermediate-, and poor-risk FLIPI scores had a 5-year OS of approximately 90%, 70%, and 35%, respectively.[256] Patients with progression within 2 years of the initial treatment were reported to have worse OS.[271] Poor risk FLIPI, older age (>60 years), and high LDH were reported to be associated with inferior outcomes of 56 NMZL patients.[272]

CHAPTER 84

DIFFUSE LARGE B-CELL LYMPHOMA OF THE CENTRAL NERVOUS SYSTEM

Syed A. Abutalib, Nilanjan Ghosh, Alexander Feldman[†], Karan S. Dixit, and Rimas V. Lukas

Diffuse large B-cell lymphoma (DLBCL) of the central nervous system (CNS) accounts for an overwhelming majority (95%) of cases of primary CNS lymphoma (PCNSL). According to the 2016 report of the World Health Organization (WHO), it is defined as DLBCL arising within the brain, spinal cord, leptomeninges, or eye.[1] The WHO definition[1] excludes lymphomas of the dura, intravascular large B-cell lymphomas (IVLBL), secondary CNS lymphomas (SCNSLs), and all immunodeficiency associated lymphomas from this category (Table 84.1). For the purpose of discussion, in this text, the terms PCNSL and DLBCL of the CNS are used interchangeably. The diagnosis and management of primary vitreoretinal lymphoma (PVRL) is also discussed, which is a subset of PCNSL. In the context of human immunodeficiency virus (HIV) infection, PCNSL is one of four acquired immunodeficiency syndrome (AIDS)-defining illnesses with distinct clinicopathologic characteristics and unique therapeutic challenges.[1–6] Secondary CNS lymphoma (SCNSL) may occur as a recurrence of previously diagnosed non-Hodgkin lymphoma (NHL) or may occur simultaneously as a manifestation of systemic disease. They can metastasize to the brain parenchyma, but more often, they spread to leptomeninges, causing symptoms across the entire neuraxis, including epidural cord compression in approximately 3% to 5% of patients.[7–9] Risk recognition and the prevention of CNS disease are important aspects of the overall management strategy in high-grade systemic DLBCLs.[9–11]

The primary origin of PCNSL is unclear, given the virtual absence of B cells in the normal brain tissue. The disease is categorized mainly as activated B cell (ABC) or non-germinal center B (non-GCB). However, the cell of origin (COO) distinction has uncertain therapeutic and prognostic merits in PCNSL.[12–15] More importantly, central to CNS lymphogenesis is the constitutive activation of B-cell receptor (BCR) signaling pathway, with its downstream target, nuclear factor-κB (NFκB), affected by frequent recurrent mutations, mainly *MYD*88 and CD79B.[16–18] From a diagnosis standpoint, the inherent challenges in timely diagnosis of PCNSL have paved the way for numerous minimally invasive diagnostic biomarkers, albeit with limited success,[19–21] in turn supporting biopsy of the affected area as the current diagnostic gold standard.

There is a paucity of high-quality comparative data to guide practitioners with level 1 evidence-based treatment recommendations for PCNSL or SCNSL. Nonetheless, unlike most other brain tumors, PCNSL often responds favorably to systemic therapy, specifically high-dose methotrexate (HD-MTX) based (poly) chemotherapy and/or whole-brain radiation therapy (WBRT). The latter modality, however, is plagued by unsustainability of responses and debilitating neurotoxicity, particularly in the older adults.[22–25] Following successful induction therapy, consolidation is administered to deepen and/or maintain the response. Overall, the treatment program of induction and consolidation attains long-term disease-free survival (DFS) in approximately 40% to 60% of the patients underscoring the fact that about half or more of the patients would relapse within the neuraxis.[26–28]

Most recently, the concept of maintenance therapy has emerged, especially for patients who are unsuitable for consolidation.[29] Novel approaches[30,31] and agents[32] are also being investigated and will be discussed throughout the chapter. The prognosis of patients who relapse, or are refractory, is dismal and treatment remains less optimally defined than for newly diagnosed PCNSL.[33] Whenever possible, patients with PCNSL and SCNSL should be guided immediately towards a well-designed, appropriately powered clinical trial.

EPIDEMIOLOGY

PCNSL accounts for less than 2% of all NHLs, 4% to 6% of all extranodal lymphomas, and 3% to 6% of all brain tumors, with an age-adjusted incidence rate of 4 cases per million persons per year.[34,35] Approximately 1500 new cases are diagnosed each year in the United States, a rate that is steadily increasing as the population ages.[35] The median age of diagnosis is 56 years in an immunocompetent host, with about an equal male-to-female ratio.[28,35] PVRL is the most common form of intraocular lymphoma (IOL). Approximately, 15% to 25% of patients with parenchymal PCNSL subsequently develop “secondary” vitreoretinal lymphoma (VRL), underscoring the importance of a bilateral eye exam at diagnosis and periodically thereafter. Conversely, about 65% to 90% of patients with PVRL consequently have or eventually develop parenchymal PCNSL, underscoring the importance of brain surveillance imaging. Primary choroidal lymphomas do not have association with CNS disease. Secondary choroidal lymphomas represent an extranodal manifestation of systemic lymphoma and are usually confined to the choroid. The most common systemic lymphoma subtype, involving the choroid, is DLBCL, followed by multiple myeloma, extramedullary plasmacytoma, Waldenström macroglobulinemia, and chronic lymphocytic leukemia (see Chapters 90, 92 and 67 respectively).

Besides advancing age, congenital and acquired immunodeficient conditions are other well-established risk factors for PCNSL (Table 84.2).[36] PCNSL, in immunocompromised individuals, occurs at an earlier age with a higher predilection for males than females.[37] It is less clear whether it follows a more aggressive course in this patient population.[37,38] In an HIV-infected individual, PCNSL is an AIDS-defining disease, associated with the Epstein-Barr virus (EBV) infection (see Chapters 78 and 87). The EBV association in an immunocompetent host with PCNSL is less frequent (<15%). The risk factors of PCNSL in HIV-infected individuals are a low CD4 count (<100,000 cells/mm ^{3}) and a high viral load. Due to effective antiretroviral therapy, the incidence of HIV-associated CNS lymphoma has been declining.

PCNSL may also present as a second malignancy.[36,39] For example, it should be considered in the differential diagnosis of patients with “recurrent disease of solid tumor” that is exclusively confined to the neuraxis or in situations where the primary systemic tumor is inactive and the patient develops a new brain lesion.

PATHOGENESIS

Despite significant progress in the elucidation of the genomic landscape of PCNSL, a specific genetic defect has not been reported. Due

TABLE 84.2 **Immunodeficiency and Primary Central Nervous System Lymphoma Incidence**

Condition	Life-time risk of PCNSL[36]
Congenital • Wiskott-Aldrich syndrome • Ataxia telangiectasia • Severe combined immunodeficiency • X-linked immunoproliferative disorder	4%
Acquired – HIV/AIDS	2%–6% (Greater risk in patients with lowest CD4+ counts)
Acquired – Non-HIV • Immunosuppressive therapy • Organ transplantation • Autoimmune disorders	Up to 7%

AIDs, Acquired immunodeficiency syndrome; *HIV*, human immunodeficiency virus; *PCNSL*, primary central nervous system lymphoma.

to its rarity and location, access to the copious tissue for diagnosis (and research) is a major limitation. Furthermore, prediagnostic and nonjudicious use of steroids in a majority of immunocompetent patients with brain mass further restricts the quantity, as well as quality, of the examined neural tissue.[40,41]

Given the virtual absence of B cells in the healthy brain parenchyma, the origin of the malignant transformation of PCNSL remains a mystery. Similar to systemic DLBCL, PCNSL is also likely to originate from late GC-derived B cells as suggested by the ongoing somatic hypermutations (SHMs) in immunoglobulin (Ig) genes. Moreover, frequent (50% to 80%) usage of the V4–34 gene segment suggests that specific antigens trigger the development of PCNSL.[42,43] Presently, no cell adhesion molecule or chemokine predicting B cell homing selectively to the brain has been identified in the evolution of PCNSL.[44]

Interestingly, concomitant small-size monoclonal B-cell populations have been identified in the peripheral blood and/or marrow in a subset of patients (~15%) with PCNSL.[45–48] In a study by Fukumura et al.,[48] individuals with tumors positive for MYD88 mutations also harbored the same mutations, albeit at a low frequency in peripheral blood mononuclear cells, suggesting that MYD88 mutation-positive precancerous cells originate outside of the CNS. Hypothetically, these cells might develop additional genetic hits that confer adaptation to the CNS environment. However, such subclinical extra-CNS clonal positivity by itself does not imply presence (or absence) of systemic lymphoma.

Additionally, a plethora of highly sophisticated experimental, albeit small studies using comparative genomic hybridization (CGH) or single-nucleotide polymorphism (SNP) array karyotyping and whole-exome sequencing (WES) techniques have highlighted myriad and heterogeneous cellular and microenvironment abnormalities, forming the contexture of PCNSL.[16–21,48–60] These abnormalities involve genes influencing chromatin structure and modification, cell-cycle regulation, adhesion molecules and immune recognition with a remarkably high prevalence of oncogenic aberrations in BCR and Toll-like receptor (TLR), triggering brisk NF-κB signaling in the majority of patients with PCNSL (Fig. 84.1A,B) (Chapters 3, 6, 12, 14, and 22).

Genomic Landscape and Aberrant Pathways

The pathogenesis of this multicompartment disease is fragmented and unclear, with a few exceptions. The CGH has identified many nonspecific genetic abnormalities.[48,50,61,62] Chromosome 6q deletions, in particular the 6q21–23, may be the most frequent alteration. They occur in about 40% to 60% of PCNSL.[63] Candidate tumor suppressors linked to chromosome 6q include: PRDM1, a tumor suppressor and regulator of terminal B-cell differentiation;[52] PTPRK, a protein tyrosine phosphatase that participates in cell adhesion signaling events;[64] and A20 (TNFAIP3), a negative regulator of NFκB signaling.[63] Along with 6p21 deletion,[54] PCNSLs frequently exhibit 9p24.1/PD-L1/PD-L2 copy number alterations and translocations, a likely genetic explanation underlying immune evasion within this immunoprivileged site.[65] Interestingly, Four et al.[66] reported high levels of PD-L1 expression with nominal PD-L1/PD-L2 translocations in 32 immunocompetent PCNSL patients. Recurrent chromosomal losses have also been detected in the 9p21 site, which encodes loci involved in cell cycle regulation, including CDKN2A, a putative target for cyclin-dependent kinase inhibitors.[63] Recurrent gains have been detected on chromosome 12, specifically in the 12q region harboring STAT6, MDM2, CDK4 and GLI1 genes.[48] Abnormalities in the long arms of chromosomes 1, 7, and 18 have also been reported.[48,50,61,62]

The BCR, TLRs, and NF-κB pathways are frequently activated due to genetic alterations, affecting in particular (see Fig. 84.1A and B): MYD88, CD79A/B, INPP50 (also called SHIP), CBL, BLNK, CARD11, MALT1, and BCL2, which foster proliferation and prevent apoptosis.[44,58,59] Other genes that have been implicated in the pathogenesis include: IRF2BP2, TBL1XR1, ETV6, IRF4, IRF2BP2, EBF1, CCND3; and CDK20, CREBBP, MLL2, ARID1A/B, and SMARCA4.[59,60,63] A recent study by Bödör et al.[51] utilized NanoString Lymphoma Subtyping Test (LST)-assay gene expression in formalin-fixed paraffin-embedded (FFPE) tissue. They elegantly showed that the most frequently mutated genes in the PCNSL cohort ($n = 64$), included MYD88 (66%), PIM1 (41%), KMT2D (31%), and PRDM1 (30%). The mutation frequencies in the remaining genes were as follows: MYC (19%), IRF4 (19%), CD79B (17%), TP53 (11%), CCND3 (9%), CARD11 (8%), PAX5 (3%), CSMD2 (3%), and CSMD3 (3%). No mutation was found in PTPRD gene. In the SCNSL cohort ($n = 12$) the PRDM1 (50%), followed by MYD88 (42%) and PIM1 (25%) were the most frequently mutated target genes. The mutation frequencies in the remaining genes proved to be lower compared to PCNSL: KMT2D (17%), CD79B (8%), IRF4 (8%), CCND3 (8%), C-MYC (8%), TP53 (8%), and PAX5 (8%). No mutation was identified in CARD11, CSMD2, CSMD3, and PTPRD genes.

Figure 84.1 (A and B) The pathogenesis of primary central nervous system lymphoma (PCNSL). There is evidence for several pathways to be critically involved in the pathogenesis of PCNSL. These have emerged as a source of novel therapeutic targets. These aberrations affect a variety of genes, which become deregulated, ultimately leading to uncontrolled proliferation, impairment of apoptosis or B-cell differentiation, or may interfere with the sensitivity of the tumor cells to immune responses in the CNS. *AKT*, Serine/threonine kinase; *aSHM*, Aberrant somatic hypermutation; *BTK*, Bruton's tyrosine kinase; *CARD11*, caspase recruitment domain family member 11; *CSR*, class switch recombination; IL-10/4, interleukin 10/4; *CXCL-13*, chemokine (C-X-C motif) ligand 13; BCR, B-cell receptor; *TLR-4*, toll-like receptor-4; *IRAK1/4*, interleukin 1 receptor associated kinase 1/4; JAK-1/2, Janus tyrosine kinase 1/2; MALT1, mucosa-associated lymphoid tissue lymphoma translocation 1 gene; *mTOR*, mammalian target of rapamycin; MYD88, myeloid differentiation factor 88; NF-κB, nuclear factor kappa-light-chain-enhancer of activated B cells; *P13K*, phosphoinositide 3-kinases; *PKC-β*, protein kinase C-β; *PD-L1*, programmed death-ligand 1; *SHM*, somatic hypermutation; *STAT 3/6*, signal transducer and activator of transcription 3/6; SYK, spleen tyrosine kinase.

identified MYD88 mutation and loss of CDKN2A as early clonal events. In a study by Balint et al.,[67] the NGS analyses revealed that over 80% of potentially protein-changing mutations in lymphomagenesis were located in eight genes: CTNNB1, PIK3CA, PTEN, ATM, KRAS, PTPN11, TP53, and JAK3. The TP53 was the only gene harboring mutation seen in all 19 patients. Inactivation of $p14^{ARF}$ and $p16^{INK4a}$ genes has also been implicated in pathogenesis.[68] Somewhat at odds with these findings are results from the study by Chapuy et al.[65] which reported the rarity of TP53 mutations. However, the p53 pathway was frequently perturbed upstream by way of a mono- or bi- allelic loss of CDKN2A. As a consequence, it is suggested that certain patients with such a mutation may benefit from MDM2/4 inhibitors that may augment wild-type p53 activity[69] and CDK-blockade.[70]

MicroRNA Expression

The discovery of microRNAs (miRNAs) has opened a new field for unraveling and therapeutically targeting diseases (see Chapter 4).[71] These small noncoding RNAs regulate diverse biological processes through posttranscriptional gene expression modulation.[71–74] A study by Fischer et al.[73] demonstrated a distinct pattern of miRNA expression in PCNSL ($n = 11$) when compared to systemic DLBCL ($n = 10$), using paraffin-embedded biopsy specimens in immunocompetent patients. In all, 18 miRNAs were differentially expressed between PCNSL and systemic DLBCL. The upregulated miRNAs in PCNSL specimens were associated with the MYC pathway (miR-17-5p, miR-20a, miR-9), with the blocking of terminal B-cell differentiation (miR-9, miR-30b/c), or with upregulation by inflammatory cytokines (miR-155). Putative tumor-suppressor miRNAs (miR-199a, miR-214, miR-193b, miR-145) were downregulated in PCNSL. There was no overlap of miRNAs dysregulated in PCNSL with those differentially expressed between IHC, defined as GCB and non-GCB types, or in those apart from miR-9, with miRNAs known to be overexpressed in human brain. Notably, the results of another study by Robertus et al.[74] are somewhat contradictory, in which they reported that miR-155 showed the lowest expression level compared with other miRNAs involved in PCNSL. This could be possibly explained by a different sample preparation, varying RNA quality, and low sample size in both studies.[73–76]

Adhesion and Chemokine Molecules

The exact mechanism behind CNS tropism and dissemination within the CNS is not clear but may be facilitated by the increased expression of extracellular matrix molecules such as LFA-1/ICAM-1,[77] CD44,[78] Fas (CD95),[79] a transmembrane receptor protein, and B cell attracting chemokines such as CXCL-12 (SDF-1) and CXCL-13 that bind to CXCR4 and CXCR5, respectively,[80] on lymphoma cells (see Fig. 84.1B) (see Chapters 11, 12, 14 and 15).

Immune Evasion and Its Implications

Loss of both human leukocyte antigen (HLA) class I and class II expression in B cell lymphomas is a mechanism of escape from a cytotoxic T lymphocyte (CTL) immune response in lymphomas of immune-privileged sites. HLA-A, HLA-B, HLA-C, and HLA-DR are variably expressed, with approximately 50% of CNS DLBCLs showing loss of major histocompatibility complex (MHC) class I and/or II expression[1,57,81] (see Chapter 24). Interestingly, Alama et al.[57] retrospectively analyzed PCNSL transcriptomes in 54 samples (sequencing, $n = 20$; microarrays, $n = 34$) from PCNSL. Integrated correlation analysis and signaling pathway topology enabled them to infer intercellular interactions. Immunohistopathology and digital imaging were used to validate the bioinformatic results. Transcriptomics allowed them to classify the tumors into three immune subtypes: immune-rich, poor, and intermediate. The immune-rich subtype was associated with better survival and characterized by hyper-activation of STAT3 signaling and other proinflammatory signaling (e.g., interferon [IFN]-γ and tumor necrosis factor [TNF]-α), resembling the hot subtype described in primary testicular lymphoma and solid tumor. A group of developmental signaling pathways including WNT/β-catenin, HIPPO (Salvador-Warts-Hippo), and NOTCH were hyper-activated in the immune-poor subtype. HLA down-modulation was associated with a low or intermediate immune infiltration and the absence of T-cell activation. Moreover, HLA class I down regulation was also correlated with worse survival, with implications for immune-intermediate PCNSL that frequently feature reduced HLA expression. A ligand–receptor intercellular network revealed a high expression of two immune checkpoints (i.e., CTLA-4/CD86 and TIM-3/LAGLS9). Mucin-domain containing protein-3 (TIM-3) and galectin-9 proteins were clearly upregulated in PCNSL (see Chapter 58). Based on their observations, they suggest testing DNA methyltransferase (DNMT) inhibitors in PTPN6 methylated PCNSL (observed in 48.5% of their study samples) to restore STAT3 expression in immune-infiltrated PCNSL, ibrutinib in combination with immune checkpoint inhibitor in immune rich/MYD88-mutated PCNSL patients (ClinicalTrials.gov Identifier: NCT03770416), and histone deacetylase (HDAC) inhibitors that crosses blood brain barrier (BBB) to re-establish the HLA class II expression in immune-poor PCNSL subtype. Miyasato et al.[82] reported that the expression of PD-1 ligands on tumor-associated macrophages (TAM) was dependent on the activation of STAT3. In addition, the expression of indoleamine 2,3-dioxygenase (IDO1) by TAMs was involved in the immune evasion by lymphoma cells in patients with PCNSL, suggesting that combination therapy using dual inhibitors of IDO1 and immune-checkpoint may have a therapeutic value. The increased incidence of IDO expression in a normal "healthy" brain with aging may help explain the increased risk of PCNSL in older patients.[83] Marcelis et al.[84] showed high expression of PD-L1 in 28% of PCNSL without amplification of the 9p24.1 locus. The TME was predominantly composed of CD8+ T cells and macrophages. The presence of the former cells was associated with an improved overall survival (OS). On the contrary, there was a correlation between high expression of TIM-3 in T cells in the TME and inferior outcome.[84] The investigators reported marked intertumoral and intratumoral heterogeneity in the TME.

Cell of Origin and Its Implications

The precise implication of COO in PCNSL remains unclear. Data using the Hans classifier show both GCB and non-GCB subtypes, but unlike nodal DLBCL (see Chapter 85), the COO IHC classification does not affect progression-free survival (PFS) or OS.[12–14,85] Limitations of these studies include small sample sizes, retrospective nature, and incomplete treatment information that could impact survival analysis. On gene expression profiling (GEP), with the limitation of sample-introduced bias, the majority of PCNSL are non-GCB subtype.[1] Interestingly, Bödör et al.[51] demonstrated a higher proportion of GCB (13% vs. 5%) and a significantly lower proportion of ABC (80% vs. 95%) PCNSL cases when compared with parallel Hans characterization. These findings are in contradiction with previous reports.[12,13,15,43,86] Such discrepancies most likely can be explained by the heterogeneity in the type and depth of the sequencing approaches (whole genome/exome sequencing vs. targeted resequencing of selected genes), the type of the analyzed material (fresh frozen vs. FFPE), and the difference between the bioinformatics pipelines and variant calling methods. The same study[51] also showed that mutations of TP53 (15% vs. 6%) and PAX5 (15% vs. 2%) were more frequent in GC cases, compared to ABC cases, respectively. While mutations of CD79B, CARD11, CSMD2, and CSMD3 were exclusively detected in ABC cases, MYD88, PRDM1, and KMT2D genes showed similar mutational frequencies across the two subtypes.[51] This finding may be of potential therapeutic relevance, as the BTK inhibitor ibrutinib has demonstrated clinical efficacy in 37% (14 of 38 patients) of nodal ABC-DLBCLs, especially in cases with concurrent MYD88 and CD79B mutations.[87] In a phase I study by Grommes et al.,[88] clinical responses were seen in 10 of 13 patients with relapsed PCNSL who had MYD88 mutation. Importantly, this study[88] showed that CARD11 mutations were associated with ibrutinib resistance.

Moreover, Montesinos-Rongen et al.[89] analyzed tissues from 21 patients with PCNSL using a microarray-based expression profile. A comparison of the transcriptional profile of PCNSL with various normal and neoplastic B-cell subsets demonstrated PCNSL (i) to display gene expression patterns most closely related to late GCB cells, (ii) to display a GEP similar to systemic DLBCLs and (iii) to be in part assigned to the ABC or the GCB subtype of DLBCL. Interestingly, their study[89] supported the notion that PCNSL exhibits characteristics associated with both ABC (IGM expression with absence of IG class switch, high frequency of somatic mutations of IG genes, recurrent 18q21 gains, activation of the NF-κB pathway, and high expression of BCL2 mRNA and protein) and GCB type (expression of BCL6, ongoing somatic hypermutation) DLBCL.[89] These data, along with the data from Fukumura et al.[48] and Inoue et al.[85] support that PCNSL represents a distinct COO entity irrespective of the conventional Hans COO classification. Additionally, a more recent, large Canadian population-based study[49] of 155 patients, suggests that PCNSL has a unique molecular profile distinct from systemic DLBCL.

Epstein-Barr Virus–Associated (Tissue-Positive) Primary Central Nervous System Lymphoma and Its Implications

EBV is most frequently observed in HIV-associated PCNSL and early posttransplant PCNSL (see Chapter 87). A recent study by Gandhi et al.[2] showed that the genetic landscape typically observed in EBV^- HIV^- PCNSL is distinct from EBV-associated PCNSL. They used targeted sequencing and digital multiplex gene expression to compare the genetic landscape and TME of 91 DLBCL histology cases. Forty-seven patients were EBV tissue-negative: 45 EBV^- HIV^- PCNSL and 2 EBV^- HIV^+ PCNSL; and 44 were EBV tissue-positive: 23 EBV^+ HIV^+ PCNSL and 21 EBV^+ HIV^- PCNSL. As noted previously, EBV^- HIV^- PCNSL had frequent MYD88, CD79B, and PIM1 mutations, and enrichment for the ABC subtype.[90] In contrast, these mutations were absent in all EBV-associated PCNSL, and ABC subtype frequency was low. Furthermore, copy number loss in HLA class I/II and antigen-presenting/processing genes was rarely observed, indicating retained antigen presentation. To counter this, EBV^+ HIV^- PCNSL had a tolerogenic TME with elevated macrophage and immune-checkpoint gene expression, whereas AIDS-related PCNSL had low CD4 gene counts. Interestingly, the proportion of PD-L1 and PD-L2 gene amplification was similar between EBV^- HIV^- PCNSL and EBV^+ HIV^- PCNSL, suggesting that the increase in expression of these ligands in EBV^+ HIV^- PCNSL may be due to macrophage expression.[84] From a therapeutic standpoint, checkpoint blockade is potentially contraindicated in post-transplant lymphoproliferative disease (PTLD) due to risk of graft rejection and graft-versus-host disease. By contrast, checkpoint blockade might be a reasonable option in AIDS-related PCNSL. Adoptive transfer of EBV-specific third-party virus specific T cells chosen on the basis of the best HLA match and in vitro effector function see (Chapters 87 and 97) has previously been shown to induce high response rates in EBV^+ PTLD and can cross the blood-brain barrier (see Chapters 87 and 97).[91,92] Based on the cumulative biological data, a phase I Australasian Leukemia/Lymphoma Group clinical trial incorporating EBV-specific third-party virus specific T cells (ACTRN12618001541291) has commenced.

CLINICAL PRESENTATION

The clinical presentation of CNS lymphoma depends on the size, pattern, and location of the disease within the neuraxis.

Brain Parenchyma

The lesions vary in size from microscopic implants to large bulky masses. PCNSL often presents in a subacute manner with chronic lethargy, nonspecific decline in cognition, and psychomotor function (32% to 43%), often delaying the diagnosis.[93] Focal neurologic deficits (56% to 70%) can be observed immediately prior to the diagnosis. Presentation of headache, confusion, diplopia, nausea, and vomiting are usually late signs and symptoms of elevated intracranial pressure (ICP). Seizures are uncommon (14%), mainly due to non-cortical location of the disease. The classic B symptoms are rarely observed in PCNSL.

Primary Vitreoretinal Lymphoma

A proportion of PCNSL patients present with PVRL.[94] Overall, visual symptoms are rare at presentation, even though the ocular involvement is relatively high (15% to 20%).[94] Insidious and nonspecific onset of symptoms can often delay the diagnosis of PVRL by 6 to 24 months. PVRL symptoms can imitate a wide range of other ocular entities and have been described as a masquerade syndrome. Patients may be asymptomatic or complain of blurred vision (40% to 50%), reduced visual acuity (25% to 30%), and vitreous floaters (20% to 25%), often misdiagnosed as inflammatory eye conditions such as uveitis, vitritis, chorioretinitis, or normal degenerative changes. The clinical signs are bilateral in approximately 60% to 90% of individuals. A history of an older adult with noninfectious uveitis who failed to respond to anti-inflammatory therapy should raise a suspicion of VRL. Other important differential diagnoses include fungal or bacterial endophthalmitis, sarcoidosis, ocular syphilis, and tuberculosis. The classic B symptoms are rarely observed in PCNSL.

Leptomeninges

Simultaneous involvement of leptomeninges is observed in a small subset (18%) of PCNSL patients, but exclusive meningeal presentation is extremely unusual. The presence of leptomeningeal involvement at diagnosis should increase suspicion of SCNSL. Symptoms of lymphomatous spinal cord lesions are parallel to those observed with other intramedullary tumors and depend on tumor location.[95,96] In general, thoracic spine is the most common area of involvement by PCNSL.[95–97]

NEUROIMAGING

Up to 75% of all PCNSLs contact a cerebrospinal fluid (CSF) surface: either the ventricular ependymal or pia lesions are often deep-seated with a predilection for the periventricular white matter, especially the corpus callosum. The basal ganglia and thalami are the next most common locations. Occasionally, PCNSLs diffusely infiltrate large areas of the hemispheres, without forming a focal cohesive mass. Widespread infiltration of lymphoma cells in both gray and white matter is characteristic. This condition—also known as lymphomatosis cerebri—is uncommon, occurring in less than 5% of cases, and is a pattern, not a distinct disease entity.

Magnetic Resonance Imaging Brain With and Without Gadolinium

The cornerstone of diagnostic testing, whenever PCNSL is suspected, is MRI with gadolinium. Over three-quarters of DLBCLs in immunocompetent patients are iso- or slightly hypointense compared with gray matter on T1 and iso- or hyperintense on T2. FLAIR signal is also usually iso or hyperintense (Fig. 84.2A–C).

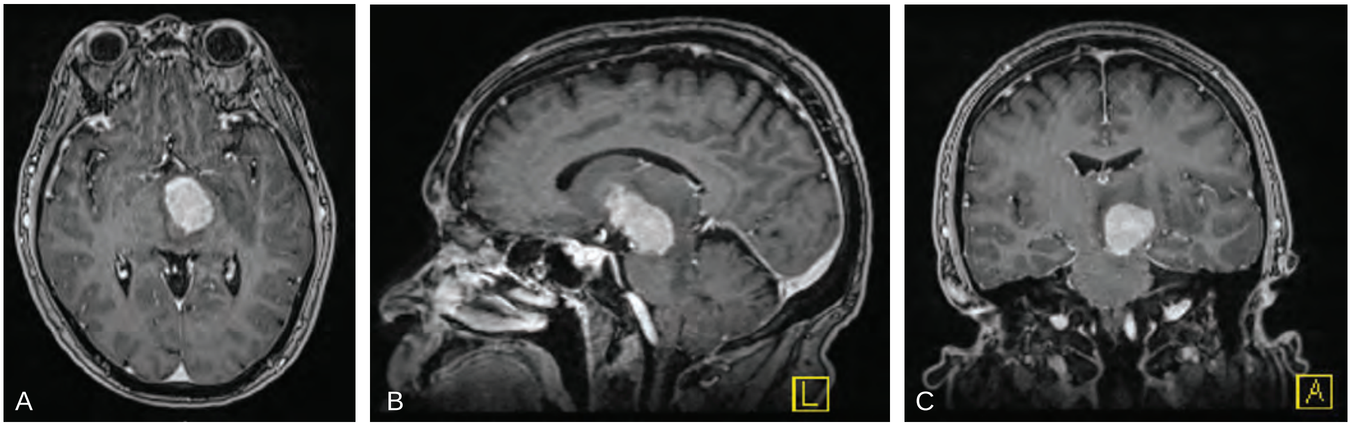

Figure 84.2 PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA IN IMMUNOCOMPETENT INDIVIDUAL. (A) T1 postcontrast axial, (B) sagittal, and (C) coronal magnetic resonance imaging images demonstrate a homogenously enhancing lesion abutting the third ventricle.

On imaging, a single lesion is present in about 60% to 70% of the PCNSL. Keeping in mind that the disease is highly infiltrative and lymphomatous, dissemination in the brain and leptomeninges may occur in the absence of contrast enhancement on magnetic resonance imaging (MRI).[98,99] Multifocal disease is observed in a substantial proportion of patients, especially at relapse, and is somewhat more common in immunocompromised individuals. Moreover, in immunocompromised patients, the enhancement may be less robust, or completely lacking (Fig. 84.3A,B). About 60% of PCNSLs involve the supratentorial space, including the frontal (15%), temporal (8%), parietal (7%), and occipital (3%) lobes, basal ganglia, periventricular brain parenchyma (10%), and corpus callosum (5%). Less frequently involved sites include the posterior fossa (13%) and spinal cord (1%).[98,99] Furthermore, diffuse enhancing supra and/or infra tentorial pachymeninges and the extension along the (sub) ependymal surfaces can be seen with contrast-enhanced MRI in about 3% to 5% of patients, which is indicative of leptomeningeal infiltration. Because of their high cellularity, over 95% of PCNSLs show mild to moderate diffusion-restriction with apparent diffusion coefficient (ADC) and diffusion weighted imaging (DWI) sequences in a nonvascular distribution.[98]

Magnetic Resonance Spectroscopy

The findings on magnetic resonance spectroscopy (MRS) are *nonspecific* and include increased choline (a marker of cell membrane transition and proliferation of cells) and lipid (a marker of tumor necrosis) peaks, a moderately decreased N-acetyl-L-aspartic acid peak (a marker of mature neurons), and a slightly decreased creatine peak (negatively associated with energy metabolism).[98] There is interest in development of novel, advanced imaging approaches to detect and provide prognostic information on PCNSL more precisely.[99]

NEUROIMAGING AND DIFFERENTIAL DIAGNOSIS PRIOR TO BIOPSY

Brain imaging, with single or multiple enhancing lesion(s), raises a broad differential diagnosis other than PCNSL which includes infectious, vascular, autoimmune, and other nonlymphoid neoplastic entities. The comprehensive clinical history as well as several specific radiographic features can assist with contraction of the differential diagnoses. Even when a nonneoplastic etiology resides atop the differential diagnosis, a stereotactic biopsy may have substantial value in clarifying the diagnosis.[100]

Stroke

Certain acute and subacute vascular events can often be confused with CNS lymphoma. Acute/subacute strokes can be enhanced on postcontrast imaging due to BBB breakdown, particularly in the subacute timeframe. Typically, this enhancement is not homogenous and usually dissipates over time. Such contrast enhancement and associated restricted diffusion follow a vascular distribution with a wedge-like appearance in medium to large vessel distribution, or more punctate enhancement in small vessel distribution. As strokes can be in multiple distributions, particularly when secondary to a cardioembolic or vasculitis source, it is not surprising that their radiographic appearance can sometimes be conflated with CNS lymphoma. The clinical pace of symptom(s) in the setting of stroke is typically sudden; however, that of CNS lymphoma is usually subacute but this by itself does not exclude the possibility of underlying stroke (see Chapter 144).

Infection

Several CNS infections, including viral, bacterial, mycobacterial, fungal, and parasitic etiologies, are associated with contrast enhancement. While the radiographic appearance does not clearly delineate an infectious etiology, the clinical presentation can provide cues to an underlying, active infection.

Immune Mediated Diseases

Certain autoimmune entities can present similarly as CNS lymphomas with regard to their subacute presentation and brain enhancement on MRI scan. For example, multiple sclerosis (MS) can mimic CNS lymphoma. However, as opposed to PCNSL in immunocompetent hosts, the median age of diagnosis is earlier in MS. Also, MS rarely presents with multiple enhancing brain lesions. Unlike PCNSL, brain enhancement is in a relatively small area in MS. The classic enhancement pattern noted in MS is an "open C" with an incomplete ring of enhancement and the open portion facing medially. Other entities that can mimic CNS lymphoma include acute disseminated encephalomyelitis (ADEM) and neurosarcoidosis. ADEM is often monophasic and can present with single, or multiple, large areas of brain enhancement. Sarcoidosis can often be a chronic process, usually with systemic involvement, along with acute/subacute exacerbations. However, even in these settings, it is often necessary to obtain CNS tissue for pathological diagnosis. All of the autoimmune entities are less likely to exhibit restricted diffusion on ADC/DWI sequences.

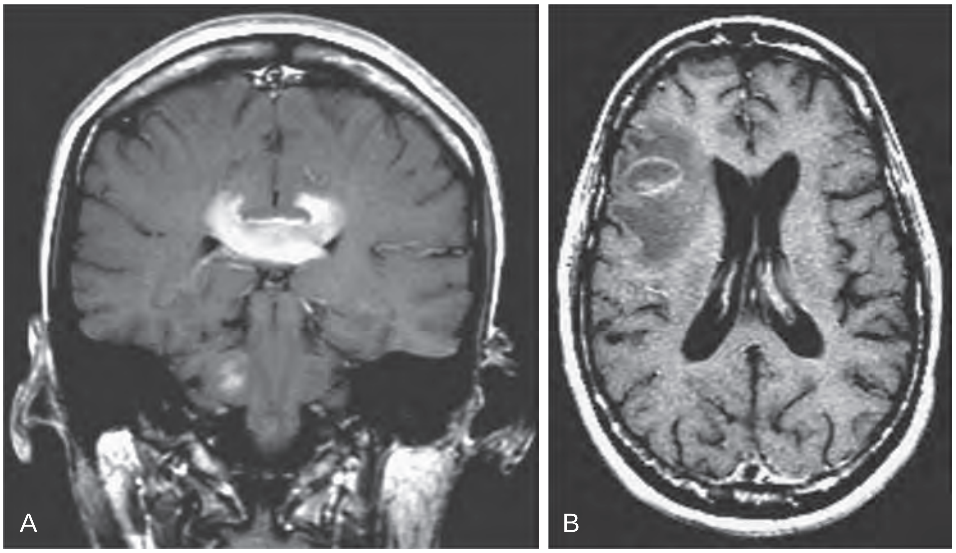

Figure 84.3 PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA IN HUMAN IMMUNODEFICIENCY VIRUS INFECTED INDIVIDUALS. (A) A coronal T1 postcontrast magnetic resonance imaging (MRI) demonstrates a large homogenously enhancing lesion crossing the corpus callosum. A second lesion of patchier enhancement can be seen in the right cerebellar peduncle. (B) An axial T1 post-contrast MRI shows a right frontal lesion with a thin rim of enhancement and a larger area of surrounding cerebral edema.

Other Central Nervous System Cancers

Infiltrating gliomas may have a similar appearance to CNS lymphoma. Both tumor types can involve the corpus callosum with thickening of the anatomic structure as opposed to the atrophy seen in MS. CNS lymphoma often involves the deeper nuclear supratentorial structures as opposed to infiltrating gliomas, which often affect cortical to subcortical brain tissue. An exception to this rule is gliomas in patients who harbor the H3K27 mutation, which is associated with involvement of deeper midline structures. Low-grade infiltrating gliomas often do not typically enhance. The enhancement pattern of high-grade gliomas (including glioblastoma) is usually heterogeneous, in contrast to the more homogenous pattern of enhancement in CNS lymphoma. In addition, the pattern of restricted diffusion on DWI and ADC sequences is often heterogeneous, when present at all, in high-grade gliomas as opposed to being homogenous in CNS lymphoma.[100]

TISSUE DIAGNOSIS

Brain Stereotactic Biopsy

The diagnostic procedure of choice, with the least risk of morbidity and mortality, remains stereotactic biopsy of the brain lesion. If ocular (vitreous, and retina) lymphoma is suspected, then surgical intervention with *timely* (tissue procurement to laboratory testing) fluid assessment is absolutely essential. Of importance, unnecessary tests should be avoided in order not to jeopardize patient care. For example, analysis of CSF should not delay stereotactic brain biopsy in a non-HIV individual, and CSF fluid testing should be done promptly in cases of suspected isolated PVRL (discussed in detail later).

Misinterpretation of Stereotactic Biopsy

Administration of steroids prior to procurement of brain tissue may significantly decrease enhancement and the size of the tumor, which in turn can easily alter the diagnosis.[40,41,101,102] It is important to inform the neuropathologist of prior systemic steroid exposure to avoid misinterpretation of specimen as "encephalitis". Biopsy should be repeated in cases where initial biopsy is inconclusive, unsatisfactory, or the diagnosis does not align with the clinical and/or radiologic presentation. In selected cases, a distinct tumor mass is not evident on imaging and/or the biopsy may have been taken from the periphery of the tumor, resulting in the finding of an entirely interstitial pattern with isolated tumor cells intermingled between astrocytes. Sometimes cases with scant tissue may show a relatively monomorphic cell population with intermingled macrophages, mimicking Burkitt lymphoma (see Chapter 85).[1]

Risks With Brain Biopsy

Most brain biopsy procedures are safely performed, but the risk of complications is about 8.5%, consisting of hemorrhage, seizures, or brain edema.[103] Biopsy-related mortality is estimated to be 0.9%.[104] Of note, the risk of hemorrhage is 11.5% in individuals with AIDS, compared to only 1% in clinically stable immunocompetent individuals.[105] For this reason, in HIV-infected individuals stereotactic biopsy may be utilized once noninvasive tests are inconclusive or undiagnostic (discussed later).[106] Current evidence does not support diagnostic or therapeutic surgical resection unless there is an impending brain herniation, or rapidly deteriorating neurologic function, failing best conservative practices. Work by some investigators supports more extensive resection.[103,107,108] However, such an approach remains non-routine.

CEREBROSPINAL FLUID ASSESSMENT FOR DIAGNOSIS

Under most circumstances, cerebrospinal fluid (CSF) analysis is no longer required in patients suspected of PCNSL. The CSF findings in PCNSL, if performed, are nonspecific and include elevated protein and lymphocytic predominant pleocytosis with normal glucose levels.[95,96,109] A routine CSF examination can only provide definitive evidence of PCNSL in the presence of extensive leptomeningeal dissemination (Fig. 84.4A–D).[95,96.109] Importantly, a misinterpretation of a peak caused by a single B cell as a monoclonal population ("pseudomonoclonality") may result in a false-positive PCR.[96] False positive results can sometimes be minimized by repeating the test and/or

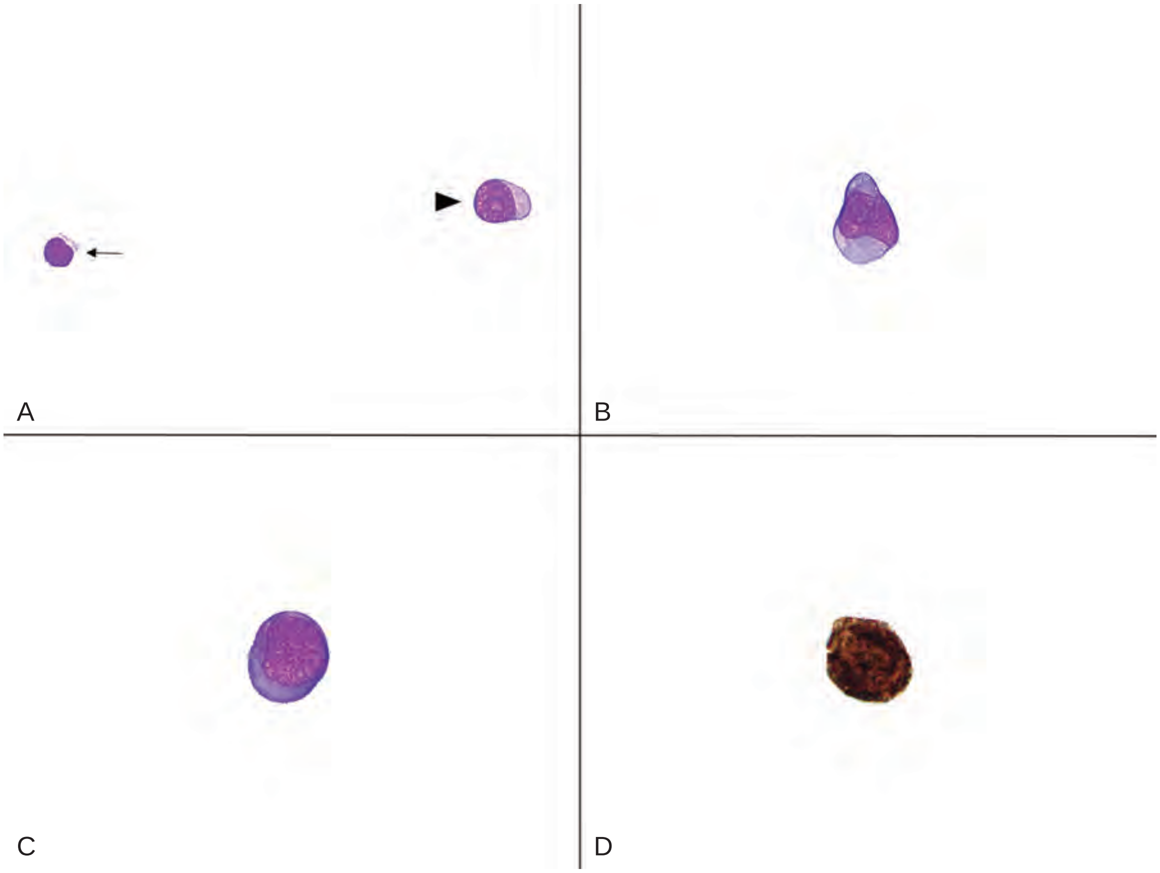

Figure 84.4 CEREBROSPINAL FLUID INVOLVEMENT BY DIFFUSE LARGE B-CELL LYMPHOMA OF THE CENTRAL NERVOUS SYSTEM. (A) In cytospin preparations the lymphoma cell (arrowhead) has a nucleus 3–4× larger than that of the nearby small lymphocyte (arrow). (B and C) Lymphoma cells show high nuclear to cytoplasmic ratios, vesicular chromatin and prominent, sometimes multiple, nucleoli. D, On cell block preparation, lymphoma cells show nuclear positivity for PAX-5, a marker of B-cell lineage. Concurrent flow cytometry of the cerebrospinal fluid confirmed a light-chain restricted large B-cell lymphoma.

through repeated PCR cycles in independent runs. Positive molecular findings in CSF should be interpreted in the context of clinical and tissue morphological data.

Cerebrospinal Fluid Testing in Human Immunodeficiency Virus–Infected Individuals

In selected cases where diagnostic brain biopsy is contraindicated and routine CSF cytology and cytometry are non-diagnostic, special tests may facilitate PCNSL diagnosis. Antinori et al.[110] reported that the combination of increased uptake on thallium-201 SPECT and a positive EBV by PCR in the CSF had 100% sensitivity and 100% negative predictive value. They suggested that patients with positive results could go directly to therapy, obviating the need for tissue biopsy. These findings are provocative and require further validation as few, if any, diagnostic studies have perfect sensitivity and specificity. In another study,[111] the sensitivity and specificity of PCR for EBV-DNA detection in CSF were 80% (95% CI: 60.9% to 91.6%) and 100% (95% CI: 92.6% to 100%), respectively.

OPHTHALMOLOGY EXAM AND VITREORETINAL SPECIMEN TESTING FOR DIAGNOSIS

In an appropriate clinical context, a comprehensive ophthalmology exam using dilated fundoscopy, fluorescent angiography, and/or optical coherent tomography is sufficient (without tissue procurement) to diagnose (primary or secondary) VRL, sparing the patient a more invasive vitreous biopsy. For example, the diagnosis of VRL can be established in an older patient with complaints of floaters, vitreous and/or subretinal cellular infiltration on exam, and positive CD20+ large cell cytology and/or flow cytometry for monoclonality in the CSF (Fig. 84.5A–C)[112]. However, in a patient with non-diagnostic CSF (as in the majority of cases) and/or brain biopsy, the gold standard for the diagnosis of VRL remains histologic identification of lymphoma cells in the vitreous and/or retina. The tissue diagnosis would require an invasive procedure, such as vitrectomy or vitreous aspirate, retinal or chorioretinal biopsy, or, rarely, diagnostic enucleation.[112,113]

The reported rates of sensitivity and specificity of cytology for the diagnosis of VRL vary widely, but cytology alone is able to confirm VRL in 45 to 60% of cases.[114,115] Alternatively, multicolor flow cytometry (MFC) has been successfully employed for phenotyping of vitreal aspirates, with a reported sensitivity of 82% and 100% specificity.[115,116] The sensitivity of clonality studies ranges between 65% and 95%, depending on the choice of primer sets and quality of material.[114] The limitations of molecular testing, particularly with the small sample size from the vitreous and/or retina, are that results could be false-positive or false-negative. In order to avoid misdiagnosis of minor clonal expansions as evidence for lymphoma, all tests should be run in duplicate to confirm the presence of a dominant clone, and results should be interpreted with caution and only in the context of clinical and morphological findings.[114] Therefore, microdissection identifying the area with most atypical lymphoid cells is critical, and if the patient has been placed on systemic or local corticosteroids, it is best to wait a few weeks to allow more of a vitreal infiltration before doing a tissue biopsy. If the biopsy is

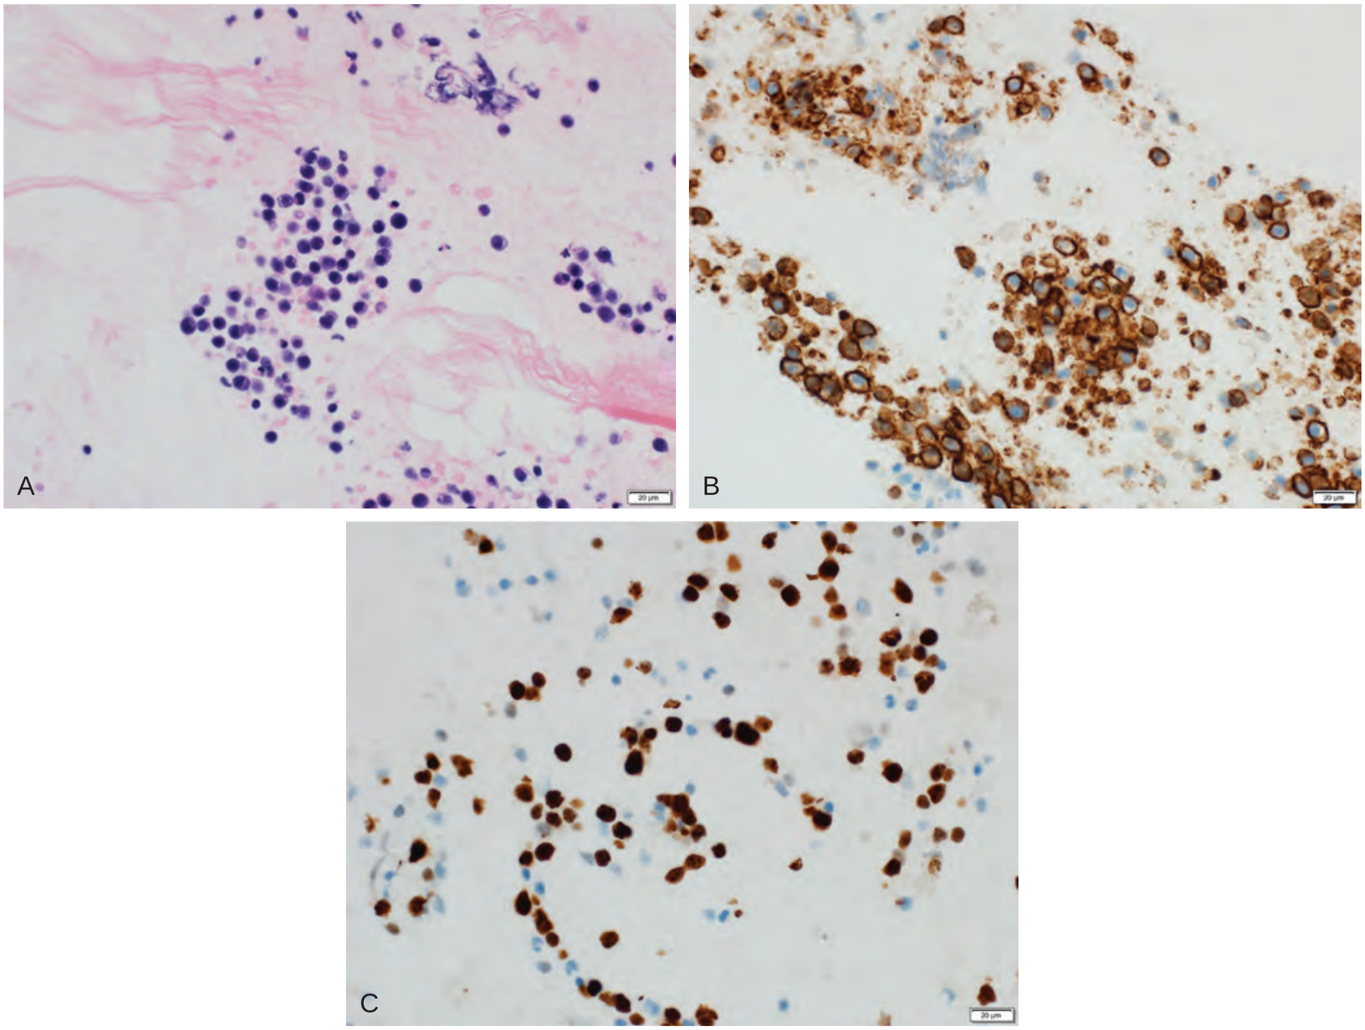

Figure 84.5 DIFFUSE LARGE B-CELL LYMPHOMA OF THE CENTRAL NERVOUS SYSTEM IN THE VITREOUS FLUID. (A) Cell block showing vitreous large B-cell lymphoma with numerous atypical large lymphocytes with irregular nuclear contours, small to moderate nuclei and scant cytoplasm (hematoxylin and eosin stain, original magnification ×400). (B) CD20 immunostain highlighting the large atypical lymphoid cells confirming B-cell lineage (CD20 immunohistochemical stain-original magnification 400×). (C) Ki-67 immunostain highlighting the large atypical lymphoid cells with a high proliferation index (Ki-67 immunohistochemical stain-original magnification 400×). *(Courtesy of Dr. Diva Salomao.)*

nondiagnostic and there is still strong suspicion of VRL, then the other vitreous should be biopsied; or if there are aggregates of subretinal cells, a retinal biopsy using the same vitrector technique with a lower cut rate and manual aspiration should be done. Additional adjuncts in diagnosing VRL exist, including elevation of interleukin-10 (IL-10) or IL-10:IL-6 ratio greater than 1 in ocular fluids, detection of *IgH*, as well as evaluation of mutant L265P MYD88 (positive in 60% to 80% of cases) and intraocular concentrations of the CD79B^{Y196} mutation.[114,117–119] In cases of mutant L265P MYD88 in the context of CD20+cells in the vitreous, a diagnosis of VRL can be confirmed.[114,117–119]

HISTOLOGY CHARACTERIZATION

Most CNS lymphomas are of B-cell origin, predominantly DLBCL. However, Burkitt lymphoma, acute lymphoblastic lymphoma, marginal zone lymphoma, extraosseous plasmacytoma, and intravascular B-cell lymphoma are rarely encountered. Moreover, less than 4% of PCNSL are of T-cell origin.[1,120] The morphology cannot discern between PCNSL and SCNSL; it is the role of staging to do so. Microscopically, the neoplastic cells are of medium to large size, with round, oval, irregular, or pleomorphic nuclei and distinct nucleoli, corresponding to centroblasts or immunoblasts, and grow in a characteristic perivascular pattern, forming concentric rings ("angiocentric" or "cuffing") (Fig. 84.6A–D).[1]

JAK/STAT signaling pathway activators such as IL-4 and IL-10 were found to be upregulated and create a favorable TME as evident by characteristic angiotropism. Rubenstein et al.[121] showed that a high expression of activated STAT6 in tumors was associated with short survival in an independent set of patients with PCNSL who were treated with HD-MTX therapy. Infiltration of cerebral blood vessels causes fragmentation of the argyrophilic fiber network. From these perivascular cuffs, tumor cells invade the neural parenchyma.[1] The TME is often accompanied by prominent microglial activation and a reactive inflammatory infiltrate, which consists of mature T cells and, sometimes, lipid-laden (foamy) histiocytes.[1] Notably, in a study by Ponzoni et al.[122], perivascular T cell infiltrates in PCNSL may predict a favorable outcome, suggesting that immunotherapeutic interventions that potentiate T-cell-mediated immune surveillance may be effective. Centrally, large areas of geographical necrosis are not uncommon making the histologic diagnosis sometimes cumbersome.[1] PCNSL does not have the degree of vascular proliferation commonly observed in glioblastoma. In the immunocompromised host, however, histologic findings of necrosis and hemorrhage are common.[1]

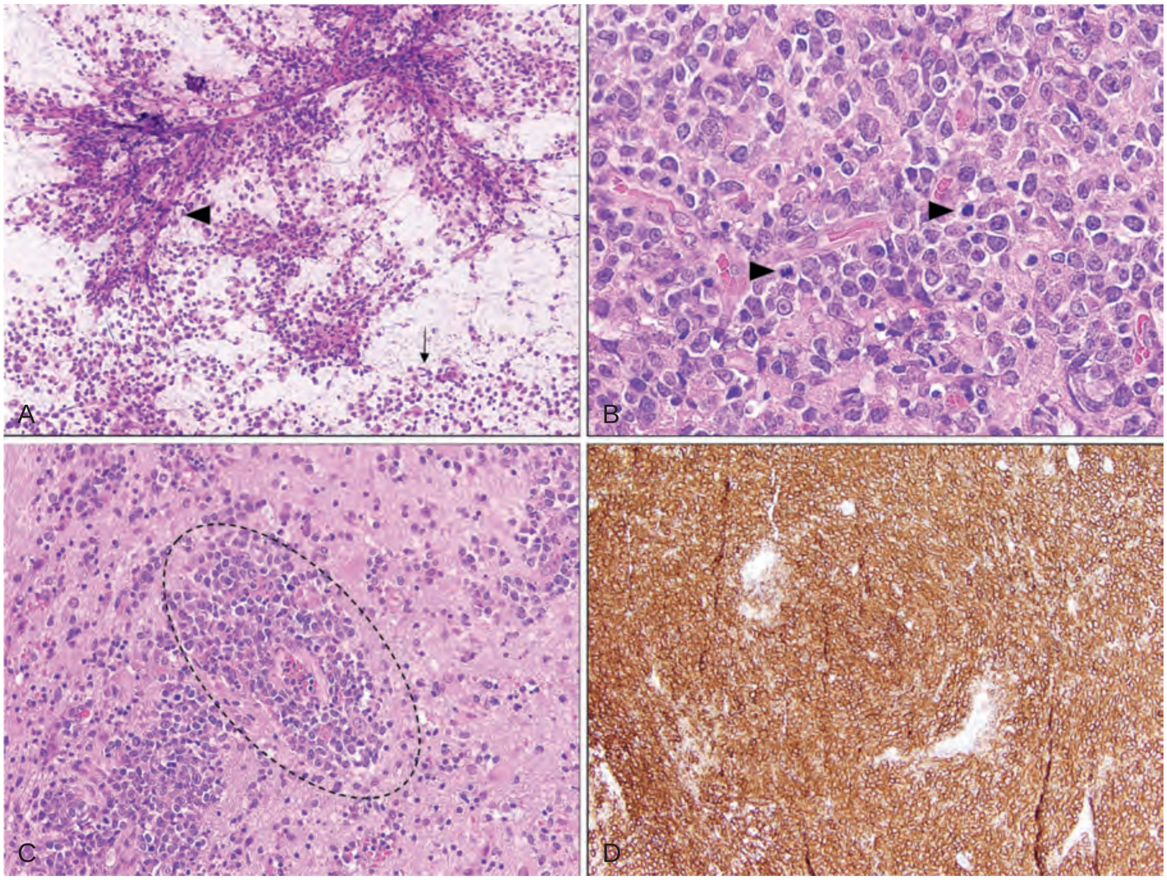

Figure 84.6 DIFFUSE LARGE B-CELL LYMPHOMA OF THE CENTRAL NERVOUS SYSTEM. (A) A squash preparation shows discohesive lymphoid cells *(arrow)* with perivascular accentuation of tumor *(arrowhead)*. (B) Hematoxylin, and eosin (H&E) sections show atypical lymphoid cells with high nuclear to cytoplasmic ratios, irregular nuclear boarders, centroblastic (multiple peripheral nucleoli) and immunoblastic (central prominent nucleoli) nuclear features and scattered mitotic figures *(arrowheads)*. (C) The periphery of the tumor is the optimal area to appreciate perivascular accentuation *(dotted oval)* and the discohesive nature of lymphoma cells. (D) The tumor cells show strong, complete membranous positivity for CD20, a marker of B-cell lineage.

The cells of PCNSL are mature B cells, with PAX5+, CD19+, CD20+, CD22+, and CD79a+ phenotypes (Fig. 84.6D).[1] IgM and IgD, but not IgG, are expressed, with either kappa or lambda light chain restriction. Most cases express BCL6 (60% to 80%) as well as MUM1 (90% to 100%), whereas plasma cell markers (i.e., CD38 and CD138) are usually not expressed. Expression of CD10 is unusual in PCNSL (<10%), and its positivity should prompt a search to exclude disseminated systemic DLBCL. Most cases (~80%) of PCNSL of the CNS are positive for BCL2 and MYC expression. However, MYC translocations are rare and BCL2 translocations are absent, suggesting that alternate mechanisms drive the protein expression in PCNSL[1,123] Conversely, BCL6 protein expression is strongly correlated with the presence of *BCL6* rearrangements. The Ki-67 is often markedly elevated; most lesions have a proliferative index that exceeds 70%. The presence of EBV should prompt evaluation for an underlying immunodeficiency. The V600E BRAF protein expression has not been detected in PCNSL.[1,124]

BIOMARKERS FOR DIAGNOSIS

Numerous biomarkers in the serum, CSF, and vitreous fluid have been evaluated with limited success[19–21] in an effort to possibly obviate the need for invasive diagnostic procedures and to expedite the diagnostic process.[125] Below are data of selected diagnostic (and in some cases prognostic) biomarkers that may be useful in clinical scenarios where diagnosis may be challenging.

Serologic Biomarkers

- **Cell-free DNA (cfDNA; liquid biopsy):** In a study by Fontanilles et al.,[126] serum cfDNA and matched tumor DNA (tDNA) from 25 PCNSL patients were sequenced. First, patient-specific targeted sequencing of identified somatic mutations in tDNA was performed. Then, a second sequencing targeting MYD88 c.T778C was performed and compared to serologic samples from 25 age-matched control patients suffering from other types of cancer. According to the patient-specific targeted sequencing, 8 patients (32% [95% CI 15 to 54%]) had detectable somatic mutations in cfDNA. Considering MYD88 sequencing, 6 patients had the specific c.T778C alteration detected. Using a control group, the sensitivity was 24% and the specificity was 100%.[126]
- **miR-21 levels:** Mao et al.[127] reported that the serum miR-21 was significantly increased in patients with PCNSL when compared with other brain tumors and normal controls in both the test and validation cohort.

Cerebrospinal Biomarkers

- **Circulating cell-free tumor DNA (ctDNA):** In the study by Grommes et al.,[128] of 9 relapsed/refractory PCNSL patients, tumor-specific ctDNA was found in the CSF of all patients. Sustained tumor responses were associated with clearance of ctDNA from the CSF.
- **IL-10:** Meta-analyses by Wang et al.[129] reported a sensitivity and a specificity of IL-10 in CSF for diagnosing CNSLs of 81%

(95% CI: 66% to 91%) and 97% (95% CI: 83% to 100%), respectively. Moreover, elevated IL-10 was associated with shorter PFS (hazard ratio: 2.89, 95% CI: 1.13 to 7.41, $P = .027$).

- **IL-10 and IL-10/IL-6 ratio:** Song et al.[19] reported a diagnostic sensitivity and a specificity of 95.5% and 96.1%, respectively (AUC, 0.957; 95% CI, 0.901 to 1.000) using an IL-10 cutoff value of 8.2 pg/mL in the CSF. In addition, the sensitivity and specificity of 95.5% and 100.0% (AUC, 0.976; 95% CI, 0.929 to 1.000), respectively, were reported using an IL-10/IL-6 cutoff value of 0.72. An increased CSF IL-10 level at diagnosis and post-treatment was associated with poor PFS for patients with PCNSL ($P = .0181$ and $P = .0002$, respectively).[19]
- **IL-10 and CXCL-13:** In the multicenter study by Rubenstein et al.[20] ($n = 220$), a bivariate elevation of IL-10 plus CXCL13 was 99.3% specific for primary and secondary CNS lymphomas, with a sensitivity two-fold greater than cytology or flow cytometry.
- **CXCL13 and CXCL9:** Masouris et al.[130] reported **a** sensitivity and a specificity of about 90% for the diagnosis of active CNSL using a cut-off value of 80 pg/mL for CXCL13. The sensitivity and specificity of CXCL9 were 61.5% and 87.1%, respectively, using a cut-off value of 84 pg/mL.
- **Soluble CD27 (sCD27):** Murase et al.[131] reported that sCD27 greater than 15 U/ml was associated with PCNSL, and inflammatory neurological diseases and not with other neurologic diseases or brain tumors.
- **Osteopontin:** This is a proinflammatory cytokine involved in immune cell activation and B-cell migration and proliferation. Strehlow et al.[132] reported significantly higher osteopontin levels (>620 ng/mL) in CNSLs compared to patients with inflammatory conditions and GBM or in healthy controls ($P < .01$). Multivariate analysis reported that high osteopontin levels were associated with shorter PFS (HR 1.61, 95 % CI 1.13 to 2.31; $P = .009$) and OS (HR 1.52, 95 % CI 1.04 to 2.21; $P = .029$).
- **Neopterin:** This is regarded as a good biomarker of immune activation mediated by the "lymphocyte-macrophage axis."[133] Viaccoz et al.[134] reported a sensitivity and a specificity of 96% and 93%, respectively, for the diagnosis of PCNSL at a neopterin cut-off value of 10 nmol/L. The positive and negative predictive values were 84% and 98%, respectively. Geng et al.[133] reported higher neopterin levels in PCNSL compared with other brain tumors and inflammatory conditions.
- **miR-21, miR-19, and miR-92a:** Baraniskin et al.[135] reported increased levels of miR-21, miR-19, and miR-92a in PCNSL. Receiver-operating characteristic analyses showed AUCs of 0.94, 0.98, and 0.97 for miR-21, miR-19, and miR-92a, respectively, in discriminating PCNSL from inflammatory and other neurologic conditions.
- **Proliferation-inducing ligand (APRIL) and B-cell activating factor (BAFF):** Mulazzani et al.[136] reported that high levels of APRIL and BAFF reliably differentiated CNSL from other focal brain lesions (including primary and metastatic brain tumors, autoimmune-inflammatory lesions, and neuroinfectious lesions) with a sensitivity of 62.3% (APRIL), 47.1% (BAFF), and a specificity of 93.7% (APRIL, BAFF).
- **Multimarker algorithm:** Maeyama et al.[137] reported a multimarker diagnostic model using CSF CXCL13, IL-10, β2-MG, and sIL-2R from the results of the case-control study and then applied the model to a prospective study ($n = 104$) to evaluate its utility. The multi-marker diagnostic algorithms had excellent diagnostic performance: the sensitivity, specificity, positive predictive value, and negative predictive value were 97%, 97%, 94%, and 99%, respectively.

Vitreous Biomarker for Vitreoretinal Lymphoma

- **miR-155:** Tuo et al.[138] reported significantly higher levels of miRNA-155 in uveitis compared to lymphoma.

Future studies with better understanding are required to validate and standardize the diagnostic utility of these and other[117,139,140] diagnostic biomarkers in primary and secondary CNSLs.

STAGING

The goal of staging in CNSL is to decipher (i) between PCNSL and SCNSL and (ii) in cases of PCNSL, to determine the extent of the disease within the neuraxis. Both of these goals can be accomplished with the tests displayed in Table 84.3, some of which are guided by individual's age, immune status, and specific signs and symptom(s), while others are performed routinely. For restaging, all the positive tests, including an ophthalmology exam, are repeated at a predetermined interval (e.g., induction and consolidation); response to therapy is categorized according to International PCNSL Collaborative Group (IPGLS) criteria[141] (described later). Cognitive testing may be performed prior to, during, and after therapy.[93] Correa et al.[142] proposed standardization of neuropsychological evaluation in PCNSL, which includes a battery of tests and a questionnaire to assess domains sensitive to disease and treatment effects such as attention, executive functions, memory, psychomotor speed, quality of life, and premorbid IQ.

TABLE 84.3 **Staging of Primary Diffuse Large B-Cell Lymphoma of the Central Nervous System**

All patients

- Brain MRI with gadolinium contrast (brain CT scan with contrast if MRI is contraindicated)
- Ophthalmologic examination including slit-lamp examination and fundoscopy to check cellular vitreal or subretinal infiltrates. Consider biomarker(s) testing in selected cases (refer to text)
- Lumbar puncture in selected cases (refer to text)
- PET-CT scan (Lugano criteria-contemporary studies demonstrate a detection of extra-CNS lymphoma in about 10% of cases (CT chest, abdomen, and pelvis if PET-CT scan unavailable)
- Bone marrow biopsy and aspirate in selected cases
- Gadolinium-enhanced MRI of the entire spine in patients with spinal cord-related sign(s) and symptom(s) or positive CSF or eye involvement.
- Testicular US in selected cases. In cases with a normal testicular exam and a negative PET-CT scan, its utility is minimal
- Infectious disease evaluation – HIV and hepatitis panel. Other infectious disease markers as clinically indicated
- Neuropsychological testing can be performed before the start of therapy and at periodic intervals. This should not delay the initiation of treatment
- Geriatric assessment in adults ≥60 years of age could be considered
- Pregnancy test (for women of reproductive potential)
- Sterility counseling/testing and referral to oncofertility for appropriate candidates

Special considerations in immunocompromised individual

- Similar to immunocompetent individuals plus
- CSF evaluation for EBV by PCR and cranial PET or single photon emission CT scan can be considered (refer to text)
- Selected cases may require additional infectious disease markers such as plasma EBV by PCR (e.g., PTLD)

CNS, Central nervous system; *CSF*, cerebrospinal fluid; *CT*, computed tomography; *EBV*, Epstein-Barr virus; *HIV*, human immunodeficiency virus; *MRI*, magnetic resonance imaging; *PCR*, polymerase chain reaction; *PET*, positron emission tomography; *PTLD*, post-transplant lymphoproliferative disease.

FRONTLINE THERAPY AND RESPONSE ASSESSMENT

Immediate Conservative Management: Best Practices

PCNSL patients who present with focal brain lesion(s) are often symptomatic at diagnosis, with an emergent to urgent requirement for therapy. Based on MRI findings, many clinicians preemptively start steroids. Priority should be given to immediate nonsteroid-based conservative management and neurosurgical consultation for immediate stereotactic biopsy. Prediagnosis steroids usually lyse the neoplastic B cells, leaving behind reactive cells that may cause false-negative interpretation of biopsy as "encephalitis", a phenomenon often referred to as "vanishing tumor". In the study by Brück et al.,[143] corticosteroids prevented diagnosis in as many as 50% of the patients. Therefore with the rare exception of impending or frank herniation, the use of prediagnostic steroids is strongly discouraged. Priority should be given to mannitol or hypertonic saline over steroids. There is no standard dosing of steroids for patients who must receive them. Also, there is no role for prophylactic anti-seizure therapy.

INDUCTION THERAPY

The treatment for patients who are deemed "medically fit" should be initiated with a HD-MTX-based regimen with the goal of achieving a complete radiologic response (CR or unconfirmed CR [CRu]), defined as a complete resolution of all enhancing diseases on the brain MRI, in the absence of corticosteroid use, for at least 2 weeks before imaging.[141] If the disease was initially noted in other CNS compartments, CR is similarly defined by the absence of disease in previously positive space(s). The consensus criteria for disease response were established by the International PCNSL Collaborative Group (IPCG),[141] and defined as follows: CR, CRu, partial response (PR), stable disease (SD), or progressive disease (PD). A CRu may still demonstrate radiographic abnormalities of uncertain significance, precluding the imaging from qualifying as a CR. Often, CRu findings are secondary to the initial diagnostic biopsy.

Commonly used induction regimens are displayed in Table 84.4. They include: HD-MTX/vincristine/procarbazine/rituximab (**MVP-R**[22]; CR of 78% [Cl not provided]); HD-MTX/temozolomide/rituximab (**MTR**[23]; CR rate of 66% [CI, 50% to 80%]); rituximab/HD-MTX/thiotepa/cytarabine (**MATRix**[24]; CR rate of 49% [95% CI 38 to 60]); and HD-MTX/BCNU/teniposide/prednisone/rituximab (**MBTP**[144]). Of high importance, the difference in induction CR rates must be interpreted in the context of the details of study design, number of patients, and specific toxicities related to each regimen. (See box on Treatment of Newly Diagnosed Adult Patient With Primary Central Nervous System Lymphoma.)

TABLE 84.4 **Commonly Utilized High-Dose Methotrexate-Based Induction Regimens in Diffuse Large B-Cell Lymphoma of the Central Nervous System**

Induction regimen	Schedule and Doses
MVP-R [22] *N* = 30	**Every 2 weeks** in patients with age between 30 and 76 years (median 57 years) **HD-MTX** 3.5 g/m^2 IV day #2 over 2 h with leucovorin rescue for 5–7 cycles. **Vincristine** 1.4 mg/m^2 (max 2.8 mg) IV day #2 **Procarbazine** 100 mg/m^2/day, orally day #7 through #13 (odd cycles only) **Rituximab** 500 mg/m^2 IV day #1 Prophylactic intrathecal chemotherapy was not administered Therapeutic intra-Ommaya MTX 12 mg was administered between days 5 and 12 of each cycle to patients with a positive CSF cytology. **Restage after the 5th cycle, and if <CR, then 2 additional cycles prior to consolidation**
MTR[23] (Alliance 50202) *N* = 43	**Every 2 weeks** in patients with age between 12 and 76 years (median 61 years) **HD-MTX** 8 g/m^2 IV day #1 over 4 h with leucovorin rescue. **Temozolomide** 150 mg/m^2 per day orally day #7 through #11 for the first 5 months (odd cycles only) **Rituximab** 375 mg/m^2 IV weekly, starting on day #3 of cycle 1, for 6 doses total No intrathecal chemotherapy was administered **Restage after 7th doses of HD-MTX with one additional HD-MTX dose in patients with CR/CRu prior to consolidation**.
MATRix[24] (IELSG32) *N* = 75	**Every 3 weeks** in patients with age between 18 and 70 years (median 57 years) **HD-MTX** 3.5 g/m^2 IV days 1 over approximately 3 h with leucovorin rescue × 4 courses **Cytarabine** 2 g/m^2 over 1 h, twice a day IV day 2, 3 **Thiotepa** 30 mg/m^2 over 30 min IV days 4 **Rituximab** 375 mg/m^2 IV days (−5), 0, Prophylactic intrathecal chemotherapy was not administered **Patients received 4 cycles prior to consolidation**
MBTP[144] (HOVON 105/ALLG NHL 24) *N* = 100	**Every 4 weeks** in patients with age between 18 and 70 years (median 61 years) **HD-MTX** 3 g/m^2 IV on days 1 and 15 with leucovorin rescue × 2 cycles **Carmustine** 100 mg/m^2 IV on day 4 **Teniposide** 100 mg/m^2/day IV days 2 and 3 **Prednisone** 60 mg/m^2/day, orally days 1 through 5 Prophylactic intrathecal chemotherapy was not administered Therapeutic IT chemotherapy in patients with positive CSF cytology after the 1st cycle **Patients received 2 cycles prior to consolidation**

CR, Complete remission; *CSF*, cerebrospinal fluid; *HD-MTX*, high-dose methotrexate; *IT MTX*, intrathecal methotrexate; *IT*, intrathecal; *IV*, intravenous; *N*, patients.

Prevention and Management of High-Dose Methotrexate Renal Toxicity

The most-feared toxicity of HD-MTX is nephropathy, caused by the precipitation of methotrexate and its metabolite 7-OH methotrexate within the renal tubules (see Chapter 58). Some protocols require a dose reduction for CrCl less than 100 mL/min, while most withhold HD-MTX for CrCl less than 50 mL/min. Delayed renal elimination can result in elevated plasma methotrexate levels for prolonged durations, with a resultant increase in systemic toxicity. Supportive measures to prevent this complication include hydration and urine alkalization with intravenous sodium bicarbonate (100 to 150 mEq/L) at 150 mL/h to maintain urine output of $\geq$100 mL/h and urine pH greater than 7.0, leucovorin rescue, and avoidance of medications that interact with methotrexate such as salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), beta-lactam antibiotics,

TREATMENT OF NEWLY DIAGNOSED ADULT PATIENT WITH PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

The patient is a 60-year-old male with a history of hypertension, diabetes, and gout. He initially developed malaise, nausea, and a feeling of lightheadedness. This was quickly followed by the subacute development of right-sided weakness. Initial workup included central nervous system imaging, which revealed a homogenously enhancing lesion involving the left thalamus and the midbrain (Fig. 84.2A–C). A biopsy was obtained, which demonstrated a diffuse large B-cell lymphoma. Molecular characterization was consistent with a nongerminal center B subtype. C-MYC expression was predominantly negative by immunohistochemistry. BCL-2 was positive in 40% on the large cells and PAX-5 was positive in all of the large cells. Ophthalmology exam was unremarkable.

The patient-initiated treatment was with curative intent. His induction regimen consisted of 2-weeks of inpatient cycles of high-dose methotrexate (HD-MTX) (8 g/m^2, day 1), temozolomide (150 mg/m^2, days 7–11, odd cycles only), and rituximab (375 mg/m^2, day 3, cycles 1–6 only) (methotrexate temozolomide and rituximab [MTR] regimen[23]). Intravenous bicarbonate was used to alkalinize the urine to facilitate excretion of methotrexate and decrease the risk of crystallization in the renal tubules, which could, in turn, impair renal function. Leucovorin was administered after methotrexate to diminish the systemic toxicity of the agent. The patient's allopurinol for his history of gout was held, as it can impair methotrexate renal clearance. Shortly after initiation of treatment, he returned to his mental (neurological) baseline. The patient received 10 doses of HD-MTX during his induction. Midway through this, an image was obtained through the magnetic resonance imaging (MRI) technique, which demonstrated a complete response by IPCNSLCG criteria.[141] This response was maintained on the postinduction MRI.

After the induction phase of the regimen he started consolidation in the inpatient setting. This consisted of high-dose etoposide (40 mg/kg continuously over 96 hours, days 1–4) and high-dose cytarabine (2 g/m^2 every 12 hours for 8 doses, days 1–[23]). The patient's course was complicated by a neutropenic fever. He was managed with growth factor support, antibiotics, antivirals, and antifungals. He was able to overcome this complication. Postconsolidation MRI demonstrated sustained CR. The patient is now a year and a half out since the completion of treatment and has no evidence of recurrence with an excellent quality of life. He is continuing with clinical and radiographic follow-up every 3 months.

sulfonamides, aminoglycosides, allopurinol, and proton pump inhibitors. Other risk factors contributing to delayed clearance of methotrexate and renal failure include high body mass index (BMI) and the presence of third-space fluid collection.

Initiate leucovorin rescue (20 to 25 mg every 6 hours) 24 hours after methotrexate infusion and continue for at least 72 hours, or until the serum MTX level is less than 0.1 μmol/L. Leucovorin is increased to 40 mg every 4 hours if serum MTX levels are in the toxic range (e.g., 24-h level $\geq$10 μmol/L, 48-h level >1 μmol/L, or 72-h level > 0.1 μmol/L). There might be a role of high-dose leucovorin, defined in one study as $\geq$4000 mg/day, given intravenously to patients who had delayed MTX clearance with levels $\geq$10 times that of toxic levels at 48 or 72 hours ($\geq$10 μmol/L at 48 hours and/or $\geq$1 μmol/L at 72 hours).[145] Additional interventions to mitigate delayed methotrexate clearance include carboxypeptidase–G2 (CPDG2, glucarpidase), a recombinant enzyme that rapidly reduces toxic serum methotrexate levels via direct hydrolysis of methotrexate, extracorporeal removal of methotrexate by means of peritoneal dialysis, and high-flux hemodialysis.[146] Finally, patients should avoid oral intake of acidic liquids while clearing HD-MTX.

CONSOLIDATION

Most patients, even those who achieve CR following HD-MTX-based induction, eventually relapse. The rationale behind consolidation therapy is to treat all residual, nonvisible (CR/CRu), and visible (PR/SD) diseases to attain, or maintain, long-term remissions. Age, performance status, comorbidities, and response to induction drive selection of the most suitable consolidation strategy. However, it must be reemphasized that there remains a lack of level 1 evidence on the choice of consolidation. Consolidation options include nonmyeloablative[23] to myeloablative[24] (autologous transplant) chemotherapy and WBRT, with doses ranging from 23.4 Gy to 45 Gy +/− chemotherapy.[22,24,144]

Whole Brain Radiation Therapy Consolidation

The timing and dose of WBRT are still unclear, given the significant risk of late neurotoxicity even at a dose of 30 Gy.[147,148] G-PCNSL-SG-1, the only phase III study in PCNSL, attempted to address the role of WBRT.[149] Patients who achieved a CR were randomized to receive 45 Gy WBRT, or observation alone, while those who did not achieve a CR were randomized to receive 45 Gy WBRT, or cytarabine. The median OS was 32.4 months (95% CI 25.8 to 39.0) in patients receiving 45 Gy WBRT ($n = 154$), and 37.1 months (27.5 to 46.7) in those not receiving WBRT ($n = 164$). The hazard ratio 1.06 (95% CI 0.80 to 1.40; $P = .71$). The median PFS was 18.3 months (95% CI 11.6 to 25.0) in patients receiving WBRT and 11.9 months (7.3 to 16.5; $P = .14$) in those not receiving WBRT (HR 0.83, Cl 0.65 to1.06, $P = .14$).[149] Treatment-related neurotoxicity in patients with sustained CR was more common in patients receiving WBRT (22 of 45, 49% by clinical assessment; 35 of 49, 71% by neuroradiology) than in those who were not (9 of 34, 26%; 16 of 35, 46%).[150] The predetermined primary endpoint for noninferiority was not met; one-third of the randomized trial population had major protocol violations; and the study was underpowered.[148,149] The question remains as to whether the elimination or deferral of WBRT is superior to a reduced and hyperfractionated dose schedule of WBRT approaches that maintain enhanced PFS without late neurocognitive toxicity. Most recently, the NRG Oncology RTOG 0227 study by Glass et al.[151] utilized the *hyperfractionated* schedule (1.2 Gy twice daily) at a lower dose of 36 Gy than what was piloted in a subset of patients who received treatment in RTOG 9310.[152] They also used temozolomide during induction (with rituximab) and 10 cycles of maintenance therapy. For patients alive at 3 years, albeit a short follow-up, none experienced a protocol-defined drop in their Mini Mental Status Examination (MMSE) score, a crude objective assessment of cognition. Sustained improvement in the quality of life (QoL) was consistent with this observation. This, at least in part, can be attributed to successful tumor treatment.[151] Another study by Morris et al.[153] used R-MVP, followed by cytarabine, and reduced-dose WBRT (23.4 Gy) for patients in whom CR was achieved. Patients who completed the regimen had a median PFS of 7.7 years and a 5-year OS of 80% (95% CI, 66% to 94%). At a short follow-up of 48 months, neuropsychological testing scores were stable. Based on these results, the RTOG is conducting a randomized phase II trial of this approach (ClinicalTrials.gov Identifier: NCT01399372). Currently, some centers do use WBRT as the consolidation in younger (age <60 years) patients. In general, lower doses are utilized in those who achieve CR, compared to patients with responses less than CR following induction (Table 84.5).[24,149–153]

Nonmyeloablative Therapy Consolidation-CALGB 50202 (Alliance 50202)

The Alliance 50202 study by Rubenstein et al.[23] did not utilize WBRT in their protocol with the objective of decreasing the risk of neurocognitive toxicity. Instead, chemotherapy was intensified with the addition of etoposide and cytarabine for patients who achieved a CR after 6 cycles (2-week cycles) of HD-MTX, temozolomide, and rituximab (MTR). Among 43 patients, 29 (66%) achieved a CR—implying that 34% of patients had radiographically visible residual disease after 6 cycles—and only 27 patients (52%) completed the entire regimen, a barrier to widespread adoption of this particular

TABLE 84.5 Selected Studies With Focus on Whole-Brain Radiation Therapy and Chemotherapy as Consolidation

Study	*N*	Median age	Induction	CR rate(s)	Consolidation	Important comments
Bromberg et al.[144]	199	61	MBVP with ($n = 99$ arm A) and without rituximab ($n = 100$ arm B [total six doses]) × 2 cycles in age up to 70 years	68% and 66%, respectively	Cytarabine × 2 cycles in patient with at least PR. Hyperfractionated WBRT (30 + 10 Gy boost to tumor site) in patients with at least PR and ≤age 60 years	HOVON 105/ALLG NHL 24 randomized phase III study • 1 years EFS (primary endpoint), where an event was no CR/CRu on protocol, relapse, or death. EFS did not differ between the arms: 1-year EFS was 49% without and 52% with rituximab • No clear benefit of addition of 6 doses of rituximab to MBTP; but longer follow-up is required. • Subgroup analysis showed that rituximab may benefit patients under 60 years of age
Glass et al.[151]	53	57	HD-MTX × 5 doses plus rituximab × 1 dose plus temozolomide daily for 5 days × 2 cycles in patient up to age 73	51%	Hyperfractionated WBRT (36 Gy) followed by temozolomide × 10 cycles	RTOG 0227 phase II study • Median follow-up for eligible patients was 3.6 years, and 2-year PFS and OS were 63.6% and 80.8%, respectively. • Cognitive function and quality of life improved, or stabilized, after hyperfractionated 36 Gy WBRT • 85% of the patients completed the entire regimen, compared to 52% in the Alliance 502020[23] study
Morris et al.[153]	52	60	R-MPV × 5–7 cycles up to age 79 years	79%	Low-dose WBRT (23.4 Gy; $n = 31$) followed by cytarabine × 2 in patients with CR	Multicenter phase II study • The 2-year PFS (primary end point) was 77% (95% CI, 63% to 92%) • Increased number of induction cycles yields higher CR rates. Also review Roth et al.[154] • Minimal neurotoxicity, albeit in a small number of survivors; no deaths from neurotoxicity have been reported • Median PFS was not reached in young patients (<60 years) and was 4.4 years in patients ≥60 years ($P = .02$) • No conclusions can be drawn about the effects of each drug when combined with HD-MTX (i.e., alkylating agent and rituximab)
Thiel et al.[149,154]	551	63	HD-MTX (4 mg/m^2) × 6 followed by HD-MTX × 6 ± ifosfamide	35%	WBRT (45 Gy; $n = 154$). Remaining patients: Cytarabine without WBRT in patients <CR	G-PCNSL-SG-1 phase III, randomized, non-inferiority trial • No significant difference in the OS (primary endpoint) was recorded when WBRT was omitted from chemotherapy • A post-hoc analysis of older adults ($n = 337$) treated with HD-MTX–based chemotherapy in the phase III trial (G-PCNSL-SG-1) reported that the median PFS and OS times after the achievement of a CR to be 16.1 and 26.7 months, respectively • Also refer to Korfel et al.[155]
Ferreri et al.[156]	79	58 and 59	HD-MTX (3.5 mg/m^2; $n = 40$) × 4 cycles vs. HD-MTX plus cytarabine ($n = 39$; 2 g/m^2 twice a day for 2 days) × 4 cycles in age up to age 75 years	18% vs. 46%, without and with cytarabine, respectively	WBRT in CR. Dose depended on age, response, and participating center (36 to 40 Gy ± boost)	Randomized phase II study • Superiority of polychemotherapy induction demonstrated in age ≤75 years • Overall response rate of 40% (CI 25–55) and 69% (CI 55–83), in HD-MTX without and with cytarabine respectively ($P = .009$) • 3-year PFS of 21% and 38%, respectively • 3-year OS of 32% and 46%, respectively

Continued

TABLE 84.5 **Selected Studies With Focus on Whole-Brain Radiation Therapy and Chemotherapy as Consolidation—cont'd**

Study	*N*	Median age	Induction	CR rate(s)	Consolidation	Important comments
Ferreri et al.[157]	41	57	MTX, cytarabine, idarubicin, thiotepa × 3 cycles up to age 70 years	76%	WBRT (30,36 and 45 Gy in CR, PR, and SD, respectively with 6 Gy boost)	Phase II study • After a median follow-up of 49 months, a plateau in the survival curve (5-year OS: 41% ± 7%) was obtained.
Fisher et al.[152]	82	NA	MPV × 5 cycles	39% after chemo	WBRT 45 Gy vs. hyperfractionated WBRT of 36 Gy if in CR. WBRT 45 Gy if not in CR after induction chemo	Secondary analysis of RTOG 93-10 study. • Although the fWBRT schedule represented a 25% reduction in biologically effective tumor dose, in comparison, PFS and OS were not significantly affected. • Neurotoxicity occurred later in the fWBRT group than in the conventional WBRT patients
Poortmans et al.[158]	52	51	MBVP × 2 cycles	69%	WBRT (30 Gy with 10 Gy boost to tumor bed) plus IT chemotherapy	• Median PFS - NR • Median OS—46 months • Neurotoxicity 12%
Bessell et al.[159]	26	59	Cyclophosphamide, doxorubicin, vincristine, and dexamethasone × 1 cycle followed by carmustine, vincristine, methotrexate, and cytarabine × 2 cycles (CHOD/BVAM)	77%	WBRT (30.6 Gy)	Reduction of the RT dose from 45 Gy to 30.6 Gy in patients younger than 60 years old with PCNSL who achieved CR resulted in an increased risk of relapse and lower OS
DeAngelis et al.[160]	98	56.5	MVP ×5 cycles and IT MTX	58%	WBRT (45 Gy) followed by cytarabine	RTOG 93-10 • First multicenter trial demonstrating improved survival with the combination of chemotherapy and WBRT, compared with previous reports of WBRT alone, but neurotoxicity (15%) was a delayed risk of this approach • Deaths ($n = 8$) from neurotoxicity • Median PFS was 24.0 months and OS was 37 months
Abrey et al.[161]	52	65	MPV × 5 cycles plus IT-MTX × 8 doses.	56%	WBRT (45 Gy; $n = 31$) plus cytarabine × 2 cycles ($n = 35$)	• Increasing the dose of MTX and adding procarbazine and vincristine improved disease control and overall survival • Median PFS 129 months • -Median OS 51 months • Neurotoxicity 30%

protocol, which may indicate a high rate of progression, toxicity, and/or intolerance. Estimated PFS at 1, 2, 3, and 4 years were 64% (95% CI, 48% to 76%), 57% (95% CI, 41% to 70%), 50% (95% CI, 34% to 64%), and 47% (95% CI). These results exceed those of other chemotherapy-alone studies[162,163] but may be inferior to the combined-modality approach with reduced-dose WBRT, albeit with less neurotoxicity.[153] The 2-year PFS for patients who completed consolidation was 0.77. Interestingly, age above 60 years ($n = 23$) did as well as younger patients ($n = 21$; $P = .48$), and the most significant clinical prognostic variable, as expected, was delay in treatments. The 3-year PFS was 0.59 (95% CI, 0.40 to 0.73) for those without a treatment delay and 0.2 (95% CI, 0.03 to 0.47) for those with a treatment delay.

Myeloablative Chemotherapy Versus Whole-Brain Radiation Therapy as Consolidation Therapy

High-dose myeloablative chemotherapy, followed by autologous hematopoietic stem cell transplantation (auto-HCT), appears to be superior relative to 45 Gy WBRT with favorable cognitive and QoL outcomes.[24,147,164] Phase II RCT PRECIS[164] compared these two approaches in 140 immunocompetent patients (age <60 years). The 2-year PFS was 87% (95% CI, 77% to 98%) versus 63% (95% CI, 49% to 81%) in auto-HCT (thiotepa, busulfan, and cyclophosphamide conditioning) and WBRT (40 Gy; 2 Gy/fraction), respectively. Cognitive impairment was observed after WBRT, whereas cognitive functions were preserved or improved after auto-HCT. Another phase II RCT-IELSG32[24] ($n = 227$ immunocompetent patients) also compared auto-HCT with carmustine and thiotepa conditioning with WBRT (age <70 years). However, with a caveat of examining three different induction regimens. The 2-year PFS rates were identical with either consolidation approach (76% ± 5%). Nonetheless, similar to the PRECIS study,[164] a significant impairment in attention and executive functioning was observed in patients who received WBRT (Table 84.6).[24]

Authors' Preference of Consolidation

At present, outside of a clinical trial, we prefer chemotherapy-based consolidation, including auto-HCT in appropriately selected

TABLE 84.6 Randomized Phase II Trials Comparing Autologous Transplant With Whole-Brain Radiation Therapy Consolidation

Study	*N*	Induction	CR rate(s)	Consolidation	Final results and comments
Houillier C et al. (2019)[164] Median age 55 years (22–60 years)	140	R-MBVP × 2 cycles ($n = 132$ intention to treat analysis; 66 patients in both consolidation arms) in age up to 60	43%	Rituximab and cytarabine × 2 cycles followed by WBRT (40 Gy; $n = 53$) or auto-HCT ($n = 44$; thiotepa, busulfan and cyclophosphamide) in all eligible patients regardless of response to induction	PRECIS • Noncomparative design of the study precludes firm conclusions • The CR rates were disappointing due to lower number and dose of HD-MTX cycles • Only 73% of the patients received consolidation after induction • The 2-year PFS rates (primary end-point) were 63% and 87% in the WBRT ($n = 38$) and auto-HCT ($n = 38$) arms, respectively • Auto-HCT mortality higher than expected due to multicenter setting and/or due to 3 drug conditioning • Neurocognitive impairment with WBRT was evident. The efficacy end points tended to favor the auto-HCT arm
Ferreri AJ et al.[24] (2017) Median age 58 years (18–70)	227	MATRix ($n = 75$) vs. MARix ($n = 69$) vs. MA ($n = 75$) × 4 cycles in age up to 70.	49%, 30%, and 23% with MATRix, MARix, and MA, respectively	WBRT ($n = 59$; 36 Gy ± 9) vs. auto-transplant ($n = 59$; thiotepa and carmustine conditioning) in patients with ≥stable disease	IELGS32 • Contribution of rituximab, and thiotepa with rituximab is evident on the backbone of methotrexate and cytarabine • MATRix was found to be superior, although with higher toxicity • At median follow-up of 30 months, patients treated with MATRix had a CR rate of 49% (95% CI 38–60), compared with 23% (14–31) of those treated with MA alone (hazard ratio 0.46, 95% CI 0.28–0.74) and 30% (CI 21–42) of those treated with MATRix (0.61, 0.40–0.94). • Randomization was stratified by IELSG risk score (low vs intermediate vs high). • The 2-year PFS rates were identical after WBRT and auto-HCT (76% ± 5%).

BCNU, carmustine; cyclophosphamide, cyclophosphamide; dox, doxorubicin; *EFS*, event-free survival; etop, etoposide; *Ifos*, ifosfamide; *IT*, intrathecal; methylpred, methylprednisolone; *MTX*, methotrexate; *NA*, not available; *OS*, overall survival; *pcb*, procarbazine; *PFS*, progression-free survival; *ritux*, rituximab; *tmz*, temozolomide; *TTP*, time to progression; *vinc*, vincristine; *WBRT*, whole-brain radiotherapy.

individuals.[24,164–167] An ongoing phase II RCT trial is comparing non-myeloablative to myeloablative (carmustine/thiotepa) consolidation in newly diagnosed patients (age 18 to 75 years) (ClinicalTrials.gov Identifier: NCT01511562; CALGB-51101) with a primary end-point of PFS.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA IN OLDER ADULTS

Approximately 50% of patients with PCNSL are older than 65 years of age.[27,28,35] In general, older adults exhibit inferior outcomes relative to young patients, with the rare exception in the CALGB 50202 study ($n = 44$), in which outcomes were similar between the two groups.[24] The large US-based population database reported that survival of elderly patients has not improved, relative to younger patients.[28] Of prime relevance, the therapy for older adults should be similar to their younger counterparts, as described in previous sections, unless prohibited by comorbid conditions, poor performance status, or short life expectancy. Expectations, however, may need to be adjusted. Chronologic age by itself should not deter the practitioner from a curative approach, and many elderly patients are probably undertreated just because of their advanced age. Comprehensive comorbidity, social, and geriatric assessments are imperative prior to and during therapy[168]. The input from the multidisciplinary support team in clinical management is known to improve overall patient outcomes.[168,169]

INDUCTION IN OLDER ADULTS—SHOULD IT BE REDUCED?

Numerous studies have shown that older adults can tolerate HD-MTX regimens.[25,154,163,166–168,170–175] Surprisingly, even patients older than 80 years of age can tolerate and benefit from such an approach when adequate supportive measures are used and renal function is properly monitored.[175] HD-MTX-based regimens are not only effective and safe but also improve QoL in a significant proportion of older adults.[175,176] A meta-analysis by Kasenda et al.[177] of 783 older adults (defined as age ≥60 years) showed that 73% received HD-MTX with a median dose of 3 g/m^2. The KPS ≥70% was the strongest prognostic factor for mortality (HR 0.50, 95% Cl −0.41 to 0.62). After a median follow-up of 40 months, HD-MTX-based therapy was associated with improved OS (HR 0.70, 95% CI 0.53 to 0.93). There was no difference between HD-MTX plus oral procarbazine or temozolomide versus more aggressive HD-MTX-based intravenous therapies including cytarabine (HR 1.39, 95% CI 0.90 to 2.15).

The phase II ANOCEF-GOELAMS randomized trial[170] treating elderly patients aged above 60 years compared HD-MTX plus temozolomide (MT; $n = 48$) with HD-MTX in combination with prednisolone, vincristine, and cytarabine for consolidation (MPVA; $n = 47$). The 1-year PFS was similar at 36% (95% CI 22 to 50) in both groups. However, the median PFS was 6.1 months (95% CI 3.8 to 11.9) in the MT group and 9.5 months (95% CI 5.3 to 13.8) in the MPVA group. Quality-of-life evaluation showed improvements in most domains ($P = .01$ to .0001) compared with baseline in both groups. In the IELSG32 study[24,178] (Table 84.6), included patients up to the age of 70 years and showed a 2-year PFS of 61% (95% CI: 55% to 67%). Unremarkably, infectious complications were more frequent in patients older than 60 years.

From a practical standpoint, compromised performance status alone should not preclude HD-MTX induction as it often improves following initial treatment, allowing for subsequent intensification.[168] A less intensive initial treatment (e.g., rituximab plus HD-MTX (3 to 4 g/m^2) could mitigate toxicity in early cycles and improve the performance score, to achieve a high cumulative relative dose intensity in subsequent cycles. In patients, whose comorbidities, especially severely compromised renal and/or cardiac function, preclude HD-MTX, alternative non-WBRT-based therapy must be explored. The options include temozolomide,[179] pemetrexed,[180.] rituximab,[181] or steroids.[182] Subsequent strategies after induction (consolidation vs. maintenance vs. observation) are individualized based on the response and performance status.[166,167,183]

AUTOLOGOUS HEMATOPOIETIC STEM CELL TRANSPLANTATION IN OLDER ADULTS AS CONSOLIDATION THERAPY

Myeloablative approach may be considered in carefully selected "physiologically fit" adults with PCNSL.[166,167] A recent, small, single-arm pilot MARiTA study by Schorb et al.[167] ($n = 14$) demonstrated that high-dose chemotherapy (busulfan/thiotepa) followed by auto-HCT is safe and highly effective in older adults as well. MARiTA reported 2-year PFS and OS rates of 92.9% (95% CI: 80% to 100%) and 92.3% (95% CI: 78% to 100%), without TRM, in highly selected older adults. As expected, grade >3 hematological toxicity was more frequent, but infectious complications were similar to those reported in the PRIMAIN study (discussed in section below).[172] These results have led to ongoing phase II of MARTA trial that will investigate age-adjusted high-dose chemotherapy (rituximab/busulfan/thiotepa), followed by autologous hematopoietic cell rescue in the elderly "fit" patient population (DRKS-ID identifier: DRKS00011932).[178] However, to determine the precise role of auto-HCT in the elderly population, phase III trials comparing an age-adapted thiotepa-containing auto-HCT approach with non-intensive approaches (e.g., R-MP protocol) could provide clarification.[168] Adequate efficient accrual would be a primary consideration for conducting such a study.

MAINTENANCE THERAPY—EMERGING CONCEPT

There has been growing interest in maintenance therapy to improve outcomes.[29,184] This strategy mainly focuses on older adults who are unsuitable for chemotherapy-based consolidation,[172,174,185] but has been tested in younger adults following consolidation.[151] However, at present, the optimal agent, or regimen, remains uncertain. All maintenance agents or regimens are highly empirical in terms of optimal dose and schedule. Trials in this particular area are underway, as displayed in Table 84.7.

TABLE 84.7 **Selected Frontline Maintenance Therapy Trials in Primary Central Nervous System Lymphoma**

ClinicalTrials.gov Identifier	Phase	Maintenance Program	Eligibility Age
NCT02623010	II	Ibrutinib	60 to 85
NCT02313389	III	Rituximab-methotrexate -temozolomide versus Observation	≥ 60
NCT03495960	II	Lenalidomide versus Procarbazine (FIORELLA)	≥70
NCT02498951	II	Obinutuzumab versus Observation	≥18

Older Frail (or "Unfit") Adults Who Are Not Candidates for Consolidation

Early studies deferred WBRT consolidation and introduced the concept of maintenance by continuation of HD-MTX at protracted intervals.[186–188] A retrospective analysis by Ambady et al.[189] showed that maintenance therapy with rituximab increased the duration of survival compared to the surveillance group (HR 0.27, 95% CI 0.08 to 0.98, $P = .046$). However, the risk of progression remained similar across both groups (HR: 0.61, 95% CI 0.26 to 1.43, $P = .259$). To test this concept further, a phase II trial is underway evaluating the efficacy of obinutuzumab, a humanized anti-CD20 monoclonal antibody, as maintenance therapy in patients unsuitable for consolidation with either auto-HCT or WBRT (ClinicalTrials.gov Identifier: NCT02498951).

In the multicenter single arm, PRIMAIN study[172] patients ≥65 years (range: 66 to 85) received 3 cycles, repeated every 42 days of rituximab (375 mg/m^2, days 1, 15, 29), HD-MTX (3 g/m^2 days 2, 16, 30), and procarbazine (60 mg/m^2 days 2 to 11; R-MP,) followed by monthly 6 cycles of maintenance procarbazine (100 mg for 5 days) given to responders. In all, 38 of 107 patients achieved CR (35.5%) and 15 (14.0%) achieved PR. The CR rate was slightly lower in patients treated with R-MP, compared with R-MP plus lomustine (31.6% vs. 37.7%); lomustine was omitted from the study due to significant toxicity. Of importance, about 40% of patients were unable to finish all 3 cycles of HD-MTX. The 1- and 2-year PFS rates were 46.3% (95% CI: 36% to 55%) and 37.3% (95% CI: 28% to 46%), and OS rates after 1- and 2- years of 56.7% (95% CI: 47% to 66%) and 47% (95% CI: 37% to 56%), respectively. Omitting lomustine was associated with similar PFS and OS and less toxicity. The study was not designed to compare R-MP ($n = 38$) with R-MPL ($n = 69$). Also, fewer patients were treated with R-MP and their follow-up was shorter; therefore, any inference regarding comparative effectiveness should be considered exploratory.[172]

A comparable multicenter single-arm phase II EORTC 26925 study[163] enrolled 50 patients aged above 60 years (median age: 72 years). Treatment consisted of HD-MTX (1 g/m^2), procarbazine, lomustine, steroids, intrathecal therapy, and cytarabine for one induction cycle, followed by 5 maintenance cycles every 6 weeks. Regarding the best response, 48% achieved a CR and 1-year PFS was 40% (95% Cl, 26% to 53%). Most patients improved or preserved their cognitive functions. In the NORDIC trial[174] the 2-year PFS was 55.6% for patients ≥66 years ($n = 27$ age 66 to 75 years) who received HD-MTX (MTR, followed by temozolomide maintenance). Furthermore, only 28% of elderly patients receiving maintenance therapy had relapse after achieving CR compared to 63% in the younger cohort ($n = 39$; age 18 to 65 years) who did not receive maintenance treatment. Median duration of response was ten months in the younger subgroup, and not reached in the elderly patient subgroup ($P = .33$). The study highlights that maintenance therapy might be able to achieve sustained remission and allow deescalation of induction, thereby reducing cumulative toxicity in older adults. Other trials have examined, or are examining the prospect of ongoing treatment with an agent, not included in the induction regimen (Table 84.7).[185] Rituximab ± lenalidomide have been used in such a manner as well, but the data are mostly anecdotal and used in the setting of relapsed/refractory disease.[190–192] A retrospective series suggested the contribution of upfront maintenance lenalidomide in prolongation of PFS in 13 patients older than age 70.[185] Overall, these findings only suggest that the maintenance therapy might be a promising alternative in patients unsuitable for consolidation.

Maintenance Therapy After Consolidation

A phase II RTOG 0227 study by Glass et al.[151] ($n = 53$; median age 57 years) evaluated temozolomide maintenance after methotrexate, temozolomide, and rituximab and hyperfractionated WBRT (36 Gy). The 2-year PFS and OS were 63.6% and 80.8%, respectively.

TREATMENT OF PRIMARY VITREORETINAL LYMPHOMA - A SUBSET OF PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

The optimal therapy for PVRL also remains unsettled. The therapy requires the combined effort of an oncologist, an ophthalmologist, and a pathologist and includes localized and/or systemic therapy Table 84.8).[94] Suboptimal concentration of chemotherapy in the eye with high local relapse rates provides the rationale for ocular directed strategies.[193] Localized therapy includes radiation and/or intraocular methotrexate and rituximab.[194–202] However, some patients have resolution of intraocular lymphoma with systemic therapy alone.[162] There is an absence of randomized trials comparing the efficacy of localized radiation, intraocular therapy, and systemic therapy.

TABLE 84.8 **Consensus Therapy Recommendations[a] for Primary Vitreoretinal Lymphoma From the 2011 Report of International Primary Central Nervous System Lymphoma Collaborative Group[94]**

Without Central Nervous System or Systemic Involvement	With Central Nervous System Involvement
(a) If only one eye is involved, use local therapy. Whether it is local intravitreal methotrexate and rituximab given alone, or external beam radiation therapy (b) If both eyes are involved, there is still a preference toward local therapy, although systemic treatment should not be excluded. The addition of intravitreal chemotherapeutic agents to systemic therapy should be considered	(a) High-dose methotrexate-based therapy (possibly with systemic rituximab) is recommended in conjunction with local therapy, given limited penetration of systemic agents into the vitreous cavity (b) Whole brain radiation therapy, in conjunction with ocular radiotherapy, should be considered in those who have failed systemic therapy and are debilitated or do not meet the criteria for more aggressive therapy such as autologous transplant

[a] Low level of evidence.

Intraocular Lymphoma Without Brain Parenchyma Involvement

In a multicenter retrospective collaborative European series by Riemens et al.,[203] which included patients ($n = 78$) with isolated PVRL, the use of systemic chemotherapy did not prevent CNS lymphoma and was associated with more severe adverse effects compared with local treatment. CNS lymphoma developed in 32% of patients who received localized ocular therapy with radiation and/or ocular chemotherapy, 43% of patients who received systemic chemotherapy, and 39% of patients who received both systemic and localized therapies. Intravitreal rituximab has been used alone or in combination with intravitreal methotrexate.[197–202] In patients with PVRL, where intravitreal rituximab was used as a single agent after discontinuation of intravitreal methotrexate due to corneal epitheliopathy, all patients responded after 1 dose of intravitreal rituximab.[199] Although 55% of patients experienced disease recurrence, the lesions resolved with a course of intravitreal rituximab plus methotrexate.[199] Mayo clinic reported their experience (1990 to 2018) of 33 patients with PVRL.[202] Interestingly, combined systemic and intraocular therapy led to higher failure-free-survival ($P = .002$) and CNS relapse-free survival ($P = .003$) with no difference in OS.[202]

Intraocular Lymphoma With Brain Parenchyma Involvement

A large retrospective study by Grimm et al.[112] reported the outcomes of HIV-negative PCNSL patients with intraocular involvement. All patients ($n = 176$) received systemic therapy for PCNSL, and 102 patients also received localized therapy (ocular radiotherapy in 79 patients and intravitreal methotrexate in 22 patients). Median PFS was prolonged in patients who received ocular-directed therapy (19 months) compared to those who did not receive it (15 months; $P = .01$). However, the initial treatment approach did not impact the OS. Multivariate analysis identified receipt of dedicated local ocular therapy as the only factor predictive of PFS ($P = .01$, HR = 1.69, 95% CI 1.12 to 2.54). Localized therapy did not lower the risk of intraocular relapse compared to patients who received systemic therapy alone ($P = .7$).

Concerns and Adverse Events With Local Therapy for Primary Vitreoretinal Lymphoma

The major concern when managing PVRL with local treatment alone is the risk of CNS dissemination, which is a devastating event that occurs in half of the patients, resulting in a 4-year OS of 32%.[112] Conversely, patients with PVRL, receiving systemic chemotherapy, had a CNS relapse at the rate of 43%, but the reported 4-year OS was superior at 85%.[194] Adverse events of ocular radiation therapy include xerophthalmia and chemosis. Radiation retinopathy can be seen with higher doses of radiation.[194] Complications of intravitreal methotrexate reported include cataract, corneal epitheliopathy, maculopathy, vitreous hemorrhage, optic atrophy, and sterile endophthalmitis. Only mild and reversible ocular side effects have been reported with intravitreal rituximab.[197–201]

REAL-WORLD TREATMENT PATTERNS AND OUTCOMES—DATA FROM POPULATION-BASED STUDIES

United States

Fallah et al.[204] analyzed 9165 HIV-negative PCNSL cases reported to the US National Cancer Database from the period of 2004 to 2013. During this time, the proportion of patients receiving chemotherapy significantly increased from 65.6% to 78.8% (P for trend <.0001), whereas the proportion receiving WBRT decreased from 37.6% to 18.8% ($P < .0001$). The OS at 3 years was 37.7% (95% CI, 36.6 to 38.8) and ranged from 14.1% for patients treated with radiation therapy alone, to 51.8% for those who received multiagent chemotherapy. There was evidence of improved survival over time (P for trend =.0002). Adjusting for the varying distribution of clinical and sociodemographic characteristics by type of treating facility, the risk of not receiving chemotherapy was significantly (31%) lower in academic/research cancer programs compared with community programs (adjusted relative risk, 0.69; 95% CI, 0.62 to 0.76; $P < .0001$). The disparities in application of chemotherapy for PCNSL underscore the need for education, especially in the community setting, where most older patients receive their care (Table 84.9).

France

Houillier et al.[27] analyzed the data of 1002 immunocompetent PCNSL patients (72% aged >60 years, median KPS 60) on behalf of French oculo-cerebral lymphoma network (LOC) from the period of 2011 to 2016. They found that younger (age <60 years) patients received consolidation treatment in 77% of cases, consisting of WBRT (54%) or auto-HCT (23%). Among older (age >60 years) patients, WBRT and auto-HCT consolidation were administered at only 9% and 2%, respectively. Despite involving a minority of patients (6% in the first line and 17% at relapse), the use of auto-HCT in first-line treatment or at relapse was observed with a promising 5-year OS of 76% in the first line and a 3-year OS of 57% after relapse; this is in line with previously published studies of auto-HCT.[165,166,205,206]

Netherlands

Van der Meulen et al.[207] reported a Dutch population-based cohort of 1673 patients with PCNSL diagnosed between 1989 and 2015. An increasing incidence of PCNSL in patients aged over 60 was noted. The OS improved over time, but only in the patients less than 70 years, probably because approximately 40% of the elderly patients did not receive any antineoplastic therapy, even in the more recent period from 2009 to 2015. The 5-year OS was 56% in patients less than 60 years of age from 2009 to 2015.

United Kingdom

Martinez-Calle et al.[208] analyzed 244 PCNSL cases of older (age ≥65 years) adults from 14 UK centers between the period of 2012 and 2017. Patients received palliative care ($n = 52$), methotrexate ± rituximab ± alkylators ($n = 74$) and methotrexate and cytarabine combinations ($n = 118$). The median methotrexate cumulative dose was 8.8 g/m^2 (range 1.5 to 21) over a median of three cycles. Higher relative dose intensity of methotrexate was associated with an improved PFS and OS after adjusting for age, performance status, and baseline parameters. The 2-year PFS and OS for patients receiving four or more induction cycles followed by consolidation ($n = 36$) were 65% and 70%, respectively (see Table 84.9).

TABLE 84.9 Real World Population-Based Studies and Outcomes in Primary Central Nervous System Lymphoma

Country	Database	Year	*N*	Survival
US[204]	National cancer database	2004–2013	9165 (HIV-negative)	OS at 3 years was 37.7%, and ranged from 14.1% for patients treated with radiation therapy alone, to 51.8% for those who received multiagent chemotherapy
France[27]	LOC network	2011–2016	1002 (HIV-negative)	The median, 2-year, and 5-year OS was 25.3 months, 51%, and 38%, respectively (<60 years: not reached, 70%, and 61%; > 60 years: 15.4 months, 44%, and 28%)
Netherlands[207]	Netherlands Cancer Registry	1989–2015	1673 (HIV-negative)	The overall 5-year age-standardized relative survival (95% confidence interval) among adult patients with PCNSL was 30% (27%–34%) in the period 2009–2015
UK[208]	UK centers × 14	2012–2017	244 (age ≥ 65 years and HIV-negative)	2-year PFS and OS for patients receiving ≥ 4 induction cycles followed by consolidation ($n = 36$), were 65% and 70%, respectively
US[209]	SEER	1992–2011	4158 (36% HIV-infected)	Among HIV-uninfected cases, the 5-year OS increased from 19.1% (1992–1994) to 30.1% (2004–2006).5-year OS among HIV-infected cases was 9.0%

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA IN THE IMMUNOCOMPROMISED HOST

Human Immunodeficiency Virus: An Acquired Immunodeficiency Syndrome–Defining Illness

PCNSL has been designated an AIDS-defining disease since 1983 and accounts for 15% of NHLs in HIV-infected individuals.[4–6]

TABLE 84.10 **Primary Central Nervous System Lymphoma in Human Immunodeficiency Virus–Infected Host Versus in Immunocompetent Host**

- Worse performance status at diagnosis
- Higher LDH levels at diagnosis
- Almost universally associated with Epstein-Barr virus infection
- Radiologic features are usually strikingly different: strong rim enhancement, bleeding within the lesion, and more likely to have multiple lesions
- Unfortunately, more likely to be treated with supportive care or whole-brain radiation therapy and excluded from most clinical trials
- Higher risk of opportunistic infections

It typically affects patients with CD4 counts less than 50 cells per microliter and is rarely seen in patients receiving ART. It is important to recall that even limited interruptions of antiretroviral therapy can lead to CD4 cell nadirs and HIV viremia, along with an increased risk of lymphoma. In the late course of the infection, many patients succumb to opportunistic infections. The treatment principles have evolved as in the immunocompetent host and mirror, as described previously, for the immunocompetent host, in addition to immediate optimization of ART therapy.[4–6,210–215] The prognosis of these patients is usually inferior, compared to the immunocompetent host, due to the presence of greater adverse features as displayed in Table 84.10. Registry data on behalf of Uldrick et al.[213] reported that survival had improved over time among cases diagnosed between 1990 and 2000, but remained poor, particularly among African-Americans. Another analysis by Olszewski et al.[216] reviewed the National Cancer Center database for patients with HIV-related PCNSL, diagnosed between 2004 and 2012. The median OS was only 3.6 months. In a multicenter study evaluating outcomes in HIV positive-patients treated at academic medical centers, the outcomes were similar to those in the HIV-negative population. Survival gains in patients with PCNSL parallel an increase in chemotherapy use. However, it was less likely to be received by patients who were older, Black, or without private insurance.[216] Like immunocompetent patients, these patients should also be given the opportunity to access the best available therapy and should be included in clinical trials.

POST-TRANSPLANT LYMPHOPROLIFERATIVE DISEASE–RELATED PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

In the setting of PTLD of the CNS, the primary approach, provided EBV is driving the disease, is to reconstitute the immune function, which may be achieved in a few cases with the reduction, or cessation, of immunosuppressive therapy. If this does not work, then the treatment is individualized on a case-by-case basis. Rituximab, (systemic or intrathecal [IT]) alone, which targets the EBV-infected CD20+ cells, is a reasonable option.[217,218] Chemotherapy should be reserved for patients who (i) fail rituximab, (ii) have EBV-negative lymphomas, (iii) need a rapid response, or (iv) have high-grade monomorphic PTLD. In a retrospective study of 22 patients treated with rituximab, the ORR was 68%.[218] The median time to treatment failure was not reached at 19 months and the estimated OS was 31 months. None of the patients died of rituximab toxicity, and all patients who progressed underwent further treatment with chemotherapy. A total of 23 patients who received chemotherapy had an ORR of 74%. The median time to treatment failure was 10.5 months and the estimated OS was 42 months. However, 26% of the patients receiving chemotherapy died of toxicity. It is unclear if this high degree of treatment-related toxicity reflects real-world clinical practice (see Chapter 87).

AUTOIMMUNE DISEASE–RELATED PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Immunosuppressive drugs given to treat autoimmune conditions *may* increase PCNSL risk, but these associations cannot explain the observed temporal increase in PCNSL rates, given the low prevalence of these conditions.[219] A recent systematic review (39 records) and meta-analysis ($n = 50$) by Kaulen et al.[220] revealed DLBCL subtype (80%) and EBV positivity (75%) in most autoimmune (AD)-PCNSL. Data, with its inherent limitations, suggests that aggressive polychemotherapy can accomplish long-term OS in AD-PCNSL, comparable to immunocompetent patients. Age above 60 years ($P = .014$) was identified as a significant prognostic factor.[220]

EXPERIMENTAL THERAPEUTICS IN PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Osmotic Blood-Brain Barrier Disruption With Cerebral Intra-Arterial Chemotherapy

Osmotic disruption of the BBB is an alternative approach to achieving higher concentrations of chemotherapy in the CNS.[221–226] Angelov et al.[224] reported a multiinstitutional experience of treating 149 patients with newly diagnosed PCNSL with mannitol BBB disruption and cerebral intraarterial methotrexate-based chemotherapy. The CR rate was 58%, with a median OS of 3.1 years and a median PFS of 1.8 years. Partial seizures were reported in about 9% of patients. Most recently, Iorio-Morin et al.[225] reported retrospective analysis using a similar type of approach in 44 patients. The median follow-up was 38 months. CR was achieved in 34 patients (79%) at a median of 7.3 months. Actuarial median survival and PFS were 45 months and 24 months, respectively. Age, performance status, and tumor location did not impact the outcome. Complications included thrombocytopenia (39%), neutropenia (20%), anemia (5%), seizures (11%), stroke (2%), and others (20%; anaphylaxis to carboplatin, sepsis, pulmonary embolism, and pneumonia). This procedurally intensive approach requires institutional expertise and has not demonstrated improved outcomes compared to systemic therapies.

NGR-Human Tumor Necrosis Factor With R-CHOP

NGR-human tumor necrosis factor (NGR-hTNF) targets CD13+ (tumor) vessels, enhances vascular permeability and CNS access of anticancer drugs, and provides the rationale for the treatment of PCNSL with R-CHOP. A phase II study by Ferreri et al.[30] reported activity and safety of R-CHOP preceded by NGR-hTNF in patients with PCNSL relapsed/refractory to HD-MTX-based chemotherapy enrolled in a phase II trial. A sample size of 28 patients was considered necessary to demonstrate improvement from 30% to 50% ORR (primary endpoint). NGR-hTNF/R-CHOP would be declared active if ≥12 responses were recorded. Treatment was well tolerated; there were no cases of unexpected toxicities, dose reductions, or interruptions. NGR-hTNF/R-CHOP was active, with confirmed tumor response in 21 patients (75%; 95% Cl, 59% to 91%), which was completed in 11 patients. Seventeen of the 21 patients with a response to treatment received consolidation (auto-HCT, WBRT, and/or lenalidomide maintenance). At a median follow-up of 21 (range, 14 to 31) months, five patients remained relapse-free and six were alive.[227] Further research on this innovative approach in CNS lymphomas is warranted.

FRONT-LINE TREATMENT CHALLENGES AND CONTROVERSIES

Therapeutic Role of Surgical Resection Followed by Induction Therapy?

In most studies, no survival benefit from subtotal or gross total resection has been observed prior to induction therapy.[227–229] However, this traditional view has been rechallenged.[108,230,231] A retrospective subset analysis of the phase III German PCNSL Study Group-1[108] trial showed improved clinical outcomes in patients undergoing subtotal ($n = 70$) or gross total resection ($n = 67$) compared with patients in the biopsy cohort ($n = 379$; 48 open and 331 stereotactic). When controlled for the number of lesions, the HR of biopsy versus subtotal, or gross total, resection remained unchanged for PFS (HR = 1.37; $P = .009$) but was smaller for OS (HR = 1.27; $P = .085$). The proponents of the biopsy approach believe that routine gross surgical resection unnecessarily delays effective systemic therapy and increases the risk of permanent neurologic deficit(s). Currently, there is insufficient evidence to routinely recommend subtotal, or gross total, surgical resection in PCNSL. However, in future, the debate will continue in favor of surgical resection, especially in patients with favorable presurgical parameters (e.g., superficial isolated lesion), when preoperative diagnosis is uncertain (PCNSL vs. glioma), or when there is substantial symptomatic mass effect.[108,230,231]

Definition of High-Dose Methotrexate, its Frequency, and Definition of Failure of High-Dose Methotrexate?

The definition of “HD-MTX” is unclear and typically ranges from 3 to 8 g/m^2. Doses of 1 g/m^2 have also been called “HD-MTX”. A direct comparison of different “HD-MTX” doses has not been performed. Also, the standardized frequency of HD-MTX (i.e., every 2 weeks vs. every 3 weeks) and which parameters precisely define the term “failure of HD-MTX” are not settled.

High-Dose Methotrexate-Based Monotherapy Versus Combination Therapy?

Retrospective and prospective phase II studies have investigated the efficacy of HD-MTX (8 mg/m^2) monotherapy and similarly demonstrated a shorter PFS when compared with HD-MTX-based combinations, especially with alkylating agent(s), vina alkaloids, and cytarabine.[22–24,144,153,156] A standardized, or perfect, recipe that goes along with HD-MTX has not been established.

Induction Cycles, Response Assessment, and Timing of Consolidation?

The optimal number of induction cycles is unclear. However, studies have shown that a longer duration of induction of HD-MTX (6 to 8 cycles) results in higher CR rates, which must be balanced with toxicity.[153,162] Interestingly, there is a lack of a standard number of induction cycles that define induction success, or failure, in addition to a lack of standardized eligibility criteria to begin consolidation. For example, phase II RCT-IELGS32 study[24] allowed consolidation therapy only in patients with ≥SD, whereas phase II RCT-PRECIS[157] allowed all patients to proceed to consolidation randomization regardless of their response to induction.

Intravenous Rituximab?

There is a controversy about whether rituximab improves outcomes in patients with PCNSL. Despite limited CSF penetration, radiographic responses have been observed with rituximab monotherapy in relapsed PCNSL patients.[181] In a newly diagnosed disease, a retrospective study from Johns Hopkins compared HD-MTX with and without rituximab.[232] The addition of rituximab led to a significant improvement in the response rate, PFS, and OS. Another retrospective study from China indicated the benefit of adding rituximab to conventional HD-MTX-based polychemotherapy.[233]

Subsequently, two randomized studies comparing rituximab plus chemotherapy to chemotherapy alone in PCNSL have been reported. First, the IELSG-32 study,[24] which compared three different induction regimens (HD-MTX and high-dose cytarabine with and without rituximab and rituximab, HD-MTX, high-dose cytarabine, and thiotepa). Responding patients were randomized to WBRT or high-dose chemotherapy followed by auto-HCT. In this phase II RCT trial, addition of rituximab to chemotherapy improved PFS [HR, 0.52 (95% CI, 0.32 to 0.86)] but not OS [HR, 0.63 (95% CI, 0.42 to 1.02)]. The comparison of rituximab versus non-rituximab arms is confounded by the presence of two different chemotherapy regimens and a second randomization after induction therapy.[24] Second, the HOVON105/ALLG NHL24 study[144] compared the MBVP regimen (HD-MTX, carmustine [BCNU] to teniposide [a drug not available in United States], and prednisone) with or without rituximab. Induction therapy was followed by consolidation with high-dose cytarabine (× 2 cycles) for patients who achieved CR or PR and, in patients aged 60 years or younger, WBRT. In this open-label randomized phase III trial, the addition of 6 doses of rituximab to induction chemotherapy showed no advantage of PFS [HR, 0.77 (95% CI, 0.52 to 1.13], or OS [HR, 0.93 (95% CI, 0.59 to 1.44]. It should be noted that both studies were not powered to measure the effect of rituximab on PFS and OS. Hence a meta-analysis was performed, which suggests a marginal benefit for PFS but not for OS. The same analysis also demonstrated lack of additional grade 3 and 4 toxicities or treatment-related mortality (TRM; RR 0.53; 95% CI, 0.20 to 1.37; low certainty) with the addition of rituximab to chemotherapy.[144] In clinical practice, rituximab is routinely administered with chemotherapy.

Prophylactic Intrathecal Chemotherapy?

There has been a notable trend away from the use of IT chemotherapy treatment in PCNSL. HD-MTX (≥3 g/m^2) yields cytotoxic levels in the CSF when infused rapidly over 2 to 3 hours, obviating the need for intrathecal chemotherapy, especially for the prevention of leptomeningeal disease.[234] The proponent of prophylactic IT therapy argues that the IT approach achieves longer drug exposures at cytotoxic concentrations in the CSF compared to HD-MTX. High-dose cytarabine can also yield significant drug concentrations in the CSF; however, levels are maintained for short duration and remain unpredictable. The lack of parenchymal brain penetration with IT therapies limits its efficacy. In a multicenter retrospective series of 370 patients with PCNSL,[235] the addition of IT chemotherapy to HD-MTX did not improve survival, even in patients with positive CSF cytology. Additionally, there was a higher incidence of neurotoxicity within IT chemotherapy. Similarly, a case-controlled retrospective study[236] reported no difference in survival between the two cohorts, that is, HD-MTX with or without IT methotrexate. In practice, there are limitations and concerns about infection in using IT chemotherapy in patients with PCNSL. Also, approximately one-third of patients present with increased intracranial pressure, limiting lumbar punctures or placement of Ommaya reservoirs.[237–239] In the absence of more definitive studies showing a survival benefit, the routine use of prophylactic IT chemotherapy remains controversial and is rarely used in PCNSL.

Therapeutic Intrathecal Chemotherapy in PCNSL?

This is also an area of controversy, except when leptomeningeal disease is the sole presentation of CNSL. In cases of CNS, parenchymal, and leptomeningeal diseases, precedence is given to systemic therapy over IT therapy in most (but not all) contemporary studies. With regard to the IT approach, methotrexate is the most widely used agent, given twice a week until clearance of CSF lymphoma cells (with multiple negative flow cytometry), followed by a minimum of two additional IT injections. Other IT chemotherapy agents include cytarabine ± steroids.[240] Triple therapy with methotrexate, cytarabine, and hydrocortisone is used.[241] There are no prospective studies guiding the choice of intrathecal agent(s) or duration of therapy.

High-Dose Methotrexate–Related Neurotoxicity

HD-MTX has been implicated in both preclinical and clinical studies and has been linked with neurotoxicity.[242] However, few studies have assessed pre- and post-treatment psychometric evaluation. Data regarding the long-term impact of HD-MTX neurotoxicity is sparse.[243,244] An international observational study by Doolittle et al., using standardized psychometric assessments with a long median follow-up of 5.5 years, demonstrated multidomain cognitive impairment in 19% of survivors and up to 47% of patients treated with WBRT.[243] Fliessbach et al.[245] performed a prospective neuropsychological and neuroimaging study in a series of 20 patients treated with HD-MTX-based (poly) chemotherapy. There was no gross cognitive decline in long-term survivors, despite therapy-induced white matter changes on posttherapy serial imaging in five patients. In comparison, after WBRT, abnormal areas of white matter abnormalities corresponded with a worse performance of patients in multiple neurocognitive domains.[164,246,247] Interestingly, some functional polymorphisms interfering with the methionine metabolism, in addition to male gender, might also influence methotrexate associated white matter changes (see box on Therapy-Related Neurotoxicity).[248]

THERAPY-RELATED NEUROTOXICITY

The patient was a 66-year-old male who would become lost while performing his job as a pizza delivery driver. This led to evaluation with MRI of the brain, which revealed multifocal homogenously enhancing lesions. The patient underwent a lumbar puncture, revealing a diffuse large B cell lymphoma (see Fig. 84.4A–D). Staging did not reveal the presence of lymphoma elsewhere. He was treated in a National Cancer Institute cooperative group study (Alliance 51101) where he received induction with high-dose methotrexate (HD-MTX), temozolomide, and rituximab. He was randomized to consolidation with a myeloablative regimen of carmustine (BCNU) and thiotepa, followed by an autologous hematopoietic cell transplant (auto-HCT).

The patient has remained disease-free for approximately 5 years. However, he has developed the insidious onset of cognitive symptoms. These include symptoms of frontal network dysfunction such as decreased attention, increased impulsivity, inappropriate behavior, and perseveration. These symptoms have impaired his activities of daily living, including his ability to drive. Neuropsychological testing and evaluation by Cognitive Neurology confirmed these deficits as well as mild memory impairment. Central nervous system imaging with magnetic resonance imaging revealed some diffuse atrophy and extensive white signal abnormalities (Fig. 84.7). FDG PET did not demonstrate the typical findings associated with Alzheimer disease. While whole-brain radiation therapy in older patients receiving HD-MTX for primary central nervous system lymphoma is very frequently associated with a fairly rapidly progressive leukoencephalopathy, methotrexate alone can be associated with a substantial nervous system injury. This is predominantly subcortical in nature and is observed most frequently in older patients. It is, however, extremely difficult to differentiate between treatment-related cognitive deficits and an underlying or concomitant neurodegenerative dementia such as Alzheimer disease.

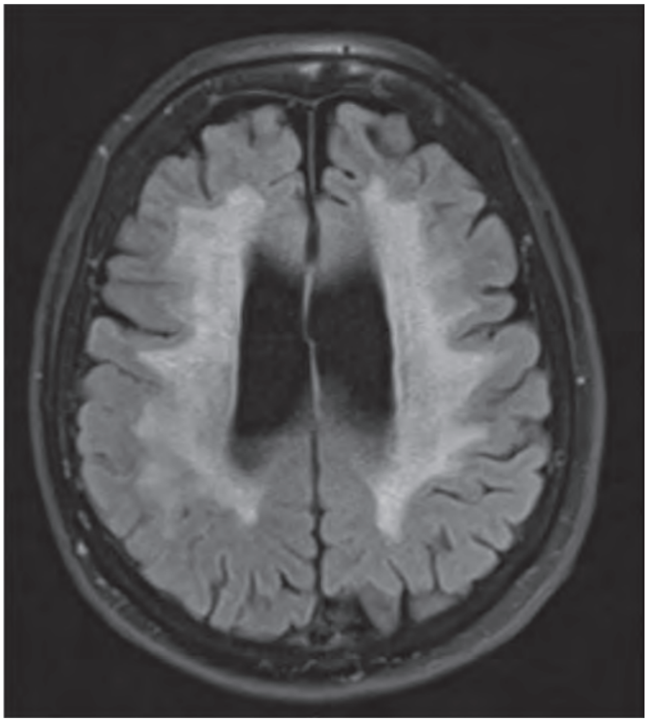

Figure 84.7 An axial magnetic resonance imaging FLAIR sequence demonstrating extensive subcortical increase in signal accompanied by clinically evident cognitive symptomatology in a patient treated with a high-dose methotrexate regimen without radiation.

Whole-Brain Radiation Therapy–Related Neurotoxicity

Patients who survive after conventional doses of WBRT are at high risk of developing potentially fatal neurotoxicity, raising the question of how to balance optimum therapy with side effects. It can affect patients of all ages, but the risk sharply increases with advancing age.[246,249,250] HD-MTX is currently the most effective and widely used chemotherapeutic agent for treatment of PCNSL, and when combined with WBRT (≥30 Gy), can manifest as early (sometimes as early as 3 months) or delayed neurotoxicity in 60% to 90% of patients.[161,247] The time course to symptomatic onset is much shorter than what is seen with focal RT for high-grade gliomas or WBRT for brain metastases, implicating that the combination with methotrexate is a likely contributing factor. The pathophysiology of radiation-induced leukoencephalopathy appears to be multifactorial and poorly understood. Depletion of oligodendrocyte progenitor cells, oxidative stress, fibrotic thickening of small vessels in the deep white matter, atherosclerosis of large intracranial vessels, as well as impaired hippocampal neurogenesis are implicated.[249,251,252] Such effects are dose-dependent and cumulative over time, making long-term survivors most vulnerable to this debilitating complication.

Common clinical presentations include attention deficit, memory impairment, psychomotor slowing, executive dysfunction, behavioral changes, urinary incontinence, and gait ataxia, consistent with diffuse subcortical dementia. These clinical findings comport with radiographic changes of progressive leukoencephalopathy (e.g., confluent periventricular and subcortical white matter abnormalities), consistent with demyelination as well as global cortical atrophy.[252] It is important to acknowledge late treatment-related retinopathy as well.[253] This complication appears to be most closely related to the combination of HD-MTX and WBRT (despite eyeball shielding), particularly in the long-term survivors. In one study, 18.5% of patients who received HD-MTX and WBRT frontline treatment developed clinically significant retinopathy by 5 years.[253]

Lower Dose of Whole-Brain Radiation Therapy?

Therapeutic doses of WBRT (40 to 45 Gy + 9 to 20 Gy boost to tumor bed) as a single modality result in neurotoxicity and disappointing PFS and median OS, in the range of 12 to 18 months with recurrences within and outside the tumor bed, leaving very few (1% to 2%) long-term survivors.[182,254,255] The addition of chemotherapy to WBRT improves CR rates and median OS but at the cost of debilitating neurotoxicity. In a multicenter phase II study, Morris et al.[153] demonstrated efficacy and better neurologic safety profile, using lower dose of WBRT (23.4 Gy) with 2 cycles of cytarabine in patients who achieved CR after 5 to 7 cycles of induction therapy with MPV-R (methotrexate, procarbazine, and vincristine-rituximab). This led to an RTOG randomized clinical trial using a similar therapeutic platform in newly diagnosed PCNSL patients who achieved CR or CRu; the final results of this trial are eagerly awaited (ClinicalTrials.gov Identifier: NCT01399372; Table 84.11). The interim results showed that the study had reached its primary endpoint. Median OS was not reached in either arm, with data still maturing.[256,257] In a retrospective series from South Korea,[258] after HD-MTX treatment, patients were treated with a reduced dose of WBRT (23.4 Gy) and a local boost or standard dose WBRT (>23.4 Gy) in cases of incomplete remission. The 3-year PFS and OS among these patients ($n = 45$) were 53.3% and 77.8% with reduced dose WBRT, and 45.8% and 58.3% with standard dose WBRT without significant difference. At present, it remains questionable whether there is a "safe and effective" dose of WBRT.[259,260]

Conditioning Regimen for Autologous Hematopoietic Stem Cell Transplantation?

Although non-thiotepa-based conditioning regimens (e.g., cyclophosphamide, carmustine; etoposide, melphalan, cyclophosphamide, dexamethasone; carmustine, etoposide, cytarabine, and melphalan) have been utilized in PCNSL and SCNSL settings,[261–265] thiotepa-based regimens (e.g., thiotepa, carmustine and etoposide[266] or thiotepa, busulfan, cyclophosphamide[165,267–269] or thiotepa and busulfan[270] or thiotepa and carmustine)[271,272] have gained more widespread clinical appreciation. Most recently, in line with previous reports the CIBMTR[273] and Japanese Society Hematopoietic Cell Transplantation Registry[274] data confirmed superior outcomes with thiotepa based regimens (Table 84.11).

Incorrect or Ambiguous Definition of the Term "Elderly"

The definition of elderly in PCNSL is nonuniform and, importantly, age cannot be used as the sole determinant to exclude patients from highly effective chemotherapy.[275–278] Despite evidence of HD-MTX showing survival benefit in older adults, spurious (in most instances) concerns of iatrogenic toxicity have led to a decreased use of effective chemotherapy.[28,275–278] An analysis of the National Cancer Database (NCDB) Participant Use File Registry among patients between the ages of 61 and 70 years old who survived longer than 3 months from diagnosis found that 14.4% did not receive any chemotherapy.[204] This fraction increased to 23.3% in patients between the ages of 71 and 80 years old and escalated to 44.1% in patients older than 80 years of age. Another recently reported retrospective analysis from NCDB, evaluating non-HIV patients with PCNSL aged above 65 years from 2004 to 2015, found that 16% of patients received no treatment.[279] Moreover, in the population-based Medicare study of 579 patients diagnosed with PCNSL from 1994 to 2002, age was inversely correlated with the chance of treatment with HD-MTX, and up to 82% of patients ≥80 years of age received either WBRT alone or no treatment at all.[280] International consensus is required to better define the biologic criteria of fitness for both induction and chemotherapy-based consolidation, including auto-HCT in older adults, to assist harmonize the design of clinical studies.[168]

TABLE 84.11 **Randomized Clinical Trials Comparing Three Consolidation Approaches (Autologous Transplantation, Reduced Dose Whole-Brain Radiation Therapy and Nonmyeloablative Chemotherapy) in Primary Central Nervous System Lymphoma**

Trial	ClinicalTrials.gov Identifier	Phase	Randomization
MATRix/ IELSG 43	NCT02531841	III	Arm 1: Rituximab, methotrexate, cytarabine, and thiotepa (4 cycles) followed by thiotepa and carmustine or busulfan-based auto-HCT Arm 2: Rituximab, methotrexate, cytarabine, and thiotepa (4 cycles) followed by dexamethasone, ifosfamide, etoposide, carboplatin (DEViC) × 2 cycles
RTOG1114[256]	NCT01399372	II	Arm 1: Rituximab, methotrexate, vincristine, and procarbazine followed by low-dose (23.40 Gy) WBRT and cytarabine × 2 cycles Arm 2: Rituximab, methotrexate, vincristine, and procarbazine followed by consolidation with single agent cytarabine × 2 cycles only
Alliance 51101	NCT01511562	II	Arm 1: Patients undergo induction therapy for five cycles as defined in the protocol followed by thiotepa and carmustine-based autologous transplant (thiotepa and carmustine conditioning regimen) Arm 2: Patients undergo induction therapy for five cycles as defined in the protocol, followed by etoposide and cytarabine consolidation therapy

PROGNOSTIC AND PREDICTIVE MARKERS

In population-based studies, the outcomes vary based upon many variables, including year and type of therapy, setting where the therapy was administered, access to care, and patient's age and immune status (Table 84.9).[27,204,207–209] It is important to reemphasize that many of the prognostic variables are modifiable and their correction would improve long-term outcomes; this has been discussed in the chapter previously. The two universally established and unmodifiable diagnostic prognostic factors include age and performance status. Both of these factors are part of two widely adopted prognostic models for PCNSL: (1) the International Extranodal Lymphoma Study Group (IESLG)[281] and (2) the Memorial Sloan-Kettering Cancer Center (MSKCC).[282]

International Extranodal Lymphoma Study Group Model[281]

This system was developed from multicenter retrospective data in immunocompetent patients ($n = 105$) treated from 1980 to 1999 and considers age (>60 years), performance status (>1), abnormal lactate dehydrogenase (LDH), high CSF protein level as defined by the study (arbitrary cutoffs of 45 mg/dL in patients ≤60 years old and 60 mg/dL in patients more than 60 years old), and radiographic location of tumor in deep regions (periventricular regions, basal ganglia, brainstem, and/or cerebellum) as unfavorable features. Points are added to create a score which estimates 2-year OS with and without HD-MTX therapy. The IESLG model reports 2-year survival rates, ranging from 15% to 85%, allowing for more nuanced discussions with patients and caregivers regarding goals of clinical management and expected outcomes. The 2-year OS ± standard deviation (SD) was 80% ± 8%, 48% ± 7%, and 15% ± 7% ($P = .00001$) for patients with 0 to 1, 2 to 3, and 4 to 5 unfavorable feature(s), respectively. The prognostic role of this model was confirmed by limiting the analysis to assessable patients treated with HD-MTX-based chemotherapy ($n = 75$; 2-year OS ± SD: 85% ± 8%, 57% ± 8%, and 24% ± 11%; $P = .0004$). Besides being a retrospective study, other limitations of this model include short follow-up of 3 years and the difficulty of attaining all the data points, particularly CSF protein, as lumbar punctures have diminishing value and/or are not always feasible at diagnosis.

Memorial Sloan-Kettering Cancer Center Model[282]

This model has greater simplicity with regard to collection of data points. However, it reflects retrospective data of immunocompetent patients ($n = 338$) treated at a single center during the period from 1983 to 2003. An external validation set obtained from three prospective RTOG PCNSL clinical trials ($n = 282$) was used to test the recursive partitioning analysis classification. It exclusively uses age and performance status to estimate median OS and failure-free survival. This system obtained three prognostic classes: class 1, patients with age ≤50 (median OS, 5.2 years; 95% CI, 3.1 to not reached); class 2, patients older than 50 with a KPS of ≥70 (median OS, 2.1 years; 95% CI, 1.4 to 2.6); and class 3, patients older than 50 plus KPS lower than 70 (median OS, 0.8 years; 95% CI, 0.5 to 1.2).

Differences Between the Two Models

Contrary to the IESLG model,[281] the MSKCC model[282] does not account specifically for therapeutic intervention and uses an age cut-off point of 50 years. As the outcome measures between the two models are different, it is difficult to make direct comparisons between them. Notably, the outcomes of older adults (>60 years to age 76 years) in the Alliance 50202 study[23] were similar to their younger (age >12 years) counterparts, a result that suggests that the optimal age cut-off may be linked to treatment variables (e.g., absence of radiation therapy) and exclusion criteria of a particular study.

Prognosis of Vitreoretinal Lymphoma With and Without Central Nervous System Parenchymal Disease

Retrospective data on behalf of IPCG ($n = 221$)[112] suggests that the natural history of patients with HIV-negative PCNSL with ocular dissemination is unaffected compared with patients with isolated parenchymal brain lymphoma. Furthermore, IESLG[281] and MSKCC[282] prognostic models, with their inherent biases, failed to identify ocular dissemination as an independent risk factor. A recent multicenter retrospective study failed to show HIV as an independent factor of disease progression and mortality. When adjusted for other variables, clinical outcomes were associated with primary treatment modalities and not with HIV status. IESLG[281] and MSKCC[282] prognostic models cannot be reliably used in PVRL.

ADDITIONAL PROGNOSTIC AND PREDICTIVE MARKERS

The following markers should also be interpreted in context of variation in treatment regimens, tissue sample sizes, and analytical procedures which may explain discrepancies between studies.

BCL-6 Overexpression and Rearrangement

In the Alliance 50202 study, BCL-6 overexpression, defined as ≥ 30%, was associated with a shorter time to progression and OS.[23] While few additional studies agree with this finding,[14,49,283] several small retrospective analyses refute it.[284,285]

c-MYC and/or BCL2 Overexpression

The study by Villa et al.[49] used tissue microarray and reported that overexpression of either of these makers is not prognostic of clinical outcomes. On the contrary, two retrospective reports using different methodologies have reported inferior outcomes with their overexpression.[286,287]

O^6-Methylguanine-DNA Methyltransferase (MGMT) Gene Promoter Methylation

In a study by Toffolatti et al.,[288] the presence of methylated MGMT promoter sequences correlated with a better OS (>60 months) in three of four patients who received high-dose chemotherapy. In another study by Adachi et al.,[289] quantitative methylation-sensitive high resolution melting analysis for the detection of MGMT promoter methylation predicted response to temozolomide. MGMT promoter methylation was detected in tumors from 23 (51%) of 45 PCNSL patients, 11 of which were considered to have a high (more than 70.0%) methylation status. Of the 5 recurrent PCNSLs treated with temozolomide, 4 cases responded, with 3 achieving CR and 1 with PR. All 4 responsive PCNSLs had methylated MGMT promoters, compared to none of the nonresponsive patients with recurrent PCNSL.

PD-1 and PD-L1

Genomic studies confirm tumor microenvironment dysfunctions in PCNSL, such as immune evasion mechanisms (e.g., *HLA* [6p21] or *B2M* [15q21.2]) copy loss, *PD-L1* (9p24.1) copy number gain, and immune communication impairments (e.g., *IL17REL* [22q13.33] copy gain or *IFNGR1* [6p23.3-q24] copy loss).[57,290] In a study by Ou et al.[291] involving patients with PCNSL, in a 42-patient cohort, high PD-L1 expression (>5% staining) was seen in 18 patients (37.5%) and intermediate expression (1% to 5% staining) was noted in 14 patients (29.2%). Sixteen patients (33.3%) lacked PD-L1 expression, suggesting that immune checkpoint therapy could be efficient against PCNSL. The presence of PD-1+ TILs and the expression of PD-L1 on malignant B cells correlated with patient outcomes.[57,65,292] A study by Four et al.[293] analyzed 32 immunocompetent patients for PD-1 and PD-L1 protein expression in both TILs and tumor cells, respectively. Presence of PD-1-positive TILs was associated with inferior overall survival ($P = .011$). Patients with PD-L1 overexpression tended to better response to chemotherapy ($P = .23$) (see Chapter 97).

MicroRNA Signature

Roth et al.[294] analyzed blood samples from patients enrolled in the G-PCNSL-SG1 trial, a phase III study for patients with newly diagnosed PCNSL. The short-term survival group comprised 20 patients with a median OS of 3 months and was compared to 20 long-term survival patients with a median OS of 55 months. The cohorts were balanced for age and performance status. Twelve annotated miRNAs were significantly deregulated between the two groups. Among them, miR-151a-5p and miR-151b exhibited the most prominent differences. Importantly, the combination of several miRNA allowed for a good separation between short- and long-term survivors with a maximal AUC above 0.75. Takashima et al.[295] analyzed 847 miRNAs expressed in 27 PCNSL specimens using microarray profiling and surveyed miRNA signatures for prognostic prediction. They reported poor prognosis with lower expression of miR-93. Yang et al.[296] reported that CSF miRNA-21 be a predictive marker to chemotherapy. Further research is warranted to maximize the clinical potential of miRNA-based diagnostics and therapeutics in PCNSL.

RELAPSED AND REFRACTORY DISEASE

Despite advances in the initial therapy, about 50% of patients relapse. The median time to relapse is between 10 and 18 months.[33] Approximately 10% to 15% of patients are refractory to initial therapy.[33] Without additional therapy, the median OS is about 2 months. The best second-line regimen for patients with relapsed and refractory PCNSL is unknown.[297] Current salvage treatments include HD-MTX rechallenge and other chemotherapy agents, auto-HCT, targeted therapies, immunomodulatory agents, immunotherapy, radiation, and allogeneic HCT. Table 84.12 highlights selected studies using a variety of agents in R/R primary and secondary CNSLs. The selection of an appropriate agent, or regimen, is a challenge given lack of prospective data.

Salvage Chemotherapy and Rituximab

Rechallenge with HD-MTX ($\geq 3\,g/m^2$) with and without other agents has shown excellent ORR of 85% to 90% with a median OS of 41 to 62 months. This is considered a reasonable approach with an acceptable toxicity profile in patients who have previously responded to methotrexate with at least 12 months of duration response.[310] Rituximab monotherapy demonstrated modest activity with a response rate of 36% and a median OS of 21 months.[181] Pemetrexed, a multi-targeted antifolate-like methotrexate, has been combined with low-dose dexamethasone. This combination yielded an ORR of 55% and a median OS of 10.1 months (range, 1.5 to 46.2 months).[300] Also, pemetrexed has been safely combined with rituximab, demonstrating an ORR of 63% and a median OS of 11.2 (95% months (CI, 9.1 to 13.4).[299] Temozolomide with or without rituximab (± steroid maintenance therapy) has demonstrated modest activity and good tolerability with response rates of 14% to 53% and 1-year OS ranging from 38% to 71%.[301,302,311,312] Topotecan is a semisynthetic camptothecin derivative that selectively inhibits topoisomerase I in the S-phase of the cell cycle and can induce long-term remissions with acceptable toxicity.[303,304] Bendamustine demonstrated a median PFS of 3.5 months (range 1 to 14 months) and a 6-month PFS of 33% in HD-MTX refractory disease.[313] Other chemotherapy combinations include procarbazine, carmustine, and vincristine (PCV)[314] and etoposide, ifosfamide, and cytarabine (VIA).[315]

Autologous Transplant

This is an attractive option in appropriately selected patients with chemosensitive disease.[206,271,316] Soussain et al.[206] utilized high-dose cytarabine and etoposide followed by a conditioning regimen of thiotepa, busulfan, and cyclophosphamide. Of 43 patients enrolled, 27 underwent transplant, with all but one patient achieving a CR with a median OS of 58.6 months. The 2-year PFS probability was 43% among all the patients and 58% in the auto-HCT subpopulation.

NON-CHEMOTHERAPEUTIC TARGETS AND AGENTS

Non-chemotherapeutic targeted agents are being increasingly tested in clinical trials. They inhibit different aspects of pathologically activated cellular pathways, unbuckle immune checkpoint inhibition, and disrupt lymphoma-nurturing TME.

Bruton Tyrosine Kinase Inhibitors

The most notable advancement is improved understanding of the Bruton tyrosine kinase (BTK) pathway in CNSLs.[65,317] Ibrutinib monotherapy (560 or 840 mg daily) showed promising clinical response with a median OS of 19.2 months.[318] Ibrutinib is also being studied in combination with chemotherapy. One such sequential combination starts with ibrutinib monotherapy followed by dose-adjusted (DA) temozolomide, etoposide, liposomal doxorubicin, dexamethasone, ibrutinib (560 to 840 mg daily) and rituximab (DA-TEDDi-R). This unique maneuvering of ibrutinib with chemotherapy and rituximab demonstrated responses in the order of 86%, with the majority of the patients achieving CR. Median PFS for the relapsed/refractory cohort was 15.3 months, with 51.3% alive at 1-year. Unfortunately, ibrutinib alone and in combination was associated with significant toxicity, including pulmonary and cerebral aspergillosis.[319,320] Additional studies are needed to improve the safety of ibrutinib. One means of doing so may be the elimination of steroids from ibrutinib-containing regimens. Ibrutinib has also been combined with HD-MTX and rituximab without significant toxicity, with an ORR of 80%, with 71% of patients alive at 1-year.[128] In this study, ibrutinib was held on days of HD-MTX and resumed 5 days after HD-MTX or after methotrexate was serologically cleared. Daily ibrutinib was administered following completion of induction therapy till disease progression, intolerability, toxicity, or death. Second-generation BTKi, tirabrutinib[321] and zanibrutinib[322] are also being investigated. In March 2020, oral tirabrutinib was approved in Japan for the treatment of recurrent or refractory PCNSL.

Immunomodulatory Agents

Lenalidomide, an oral second-generation immunomodulatory agent with CNS penetrating capability, has been evaluated as monotherapy (15 mg daily) and in combination with rituximab.[191,306] In a dose-escalating phase I study of heavily pretreated and older adults, 50% of patients achieved a response, allowing six patients to maintain responses for ≥9 months and four to maintain responses ≥18 months.[191,323] The study provided some clinical evidence for the activation of the indoleamine 2,3 dioxygenase (IDO) pathway and showed that changes in CSF IL-10 at 1 month correlated with clinical response and duration (refer to pathogenesis section). Another study demonstrated response in 64% of patients, including those with CSF and intraocular disease.[192] Lenalidomide was also safely combined with rituximab ($R^2 \times 8$ cycles followed by 12 months of maintenance).[306] This combination showed end of induction (primary-endpoint), an overall response rate of 35.6% (95% CI 21.9 to 51.2) in assessable patients, and 32.0% (95% CI 21.9 to 51.2) in the intent-to-treat analysis, including 13 CRs/CRu 29% and 3 PR (7%). With a median follow-up of 19.2 months (range 1.5 to 31), the median PFS and OS were 7.8 months (95% CI 3.9 to 11.3) and 17.7 months (95% CI 12.9 to not reached), respectively.[306] No unexpected toxicity was observed. Pomalidomide (5 mg daily for 21 days of a 28-day cycle), also an immunomodulatory agent, coupled with dexamethasone (40 mg weekly × 2 months), was studied in

TABLE 84.12 Selected Studies in Relapsed and Refractory Central Nervous System Lymphomas

Reference	Regimen	Dose and Schedule	Patients, *N*	Median Age (y)	Complete Response *N* (%)	Partial Response *N* (%)	mPFS(months)	mOS (months)
Dietrich et al. [298]	Pemetrexed	600–1200 mg/m^2 every 2 weeks (MTD: 900 mg/m^2 every 2 weeks)	17 (14 evaluable for response)	64	3 (21)	5 (36)	42	44.5

HD-MTX, High-dose methotrexate *mPFS*, median progression free survival; *mOS*, median overall survival; *NR*, not reported; *TMZ*, temozolomide.

relapsed/refractory PCNSL (n = 23) and PRVL (n = 2), showing ORRs of 48% (95% Cl, 27.8% to 68.7%).[307] Lenalidomide is being investigated in a phase I NCI trial in frontline setting with HD-MTX, rituximab with and without nivolumab (ClinicalTrials.gov Identifier: NCT04609046). In another trial, pomalidomide has been combined with nivolumab in patients with relapsed/refractory PCNSL. (ClinicalTrials.gov Identifier: NCT03798314)

mTOR Inhibitor

Temsirolimus showed some activity (dose of 75 mg weekly) with an ORR of 54% and median PFS of 2.1 months (95% CI, 1.1 to 3.0 months) at the expense of 13.5% treatment-related mortality with severe infections in 18.9% of patients.[308]

Intrathecal Rituximab as Monotherapy

Schulz et al.[241] reported their experience using direct intraventricular/intrathecal rituximab (10 to 40 mg) in six patients with recurrent PCNSL/SCNSL. Relevant toxicity was acute reversible (4-hour duration) paraparesis in one patient. Responses were seen in all four patients with leptomeningeal disease, while no responses were observed in two patients with parenchymal CNSL. Subsequently, a phase I study (n = 10) with rituximab monotherapy in a recurrent setting reported cytologic responses in six patients; four patients exhibited CR. Two patients experienced improvement in IOL and one exhibited resolution of parenchymal disease.[324] Most recently, Kadoch et al.[325] provided the first evidence of C3 (complement 3) activation within the neuraxis with intraventricular rituximab and suggested that the complement system may contribute to immunotherapeutic responses of rituximab in CNS lymphoma. They suggested that the presence of tumor-infiltrating CD14+ macrophages may portend a better treatment response as these cells provide complement and Fc receptors needed for rituximab to be effective.

Intrathecal Rituximab in Combination

Rubenstein et al.[326] (n = 14) conducted a phase I study in recurrent PCNSL/SCNSL and found that intraventricular methotrexate, combined with rituximab (10 or 25 mg twice weekly for 4 weeks), is feasible and effective. They reported 75% rate of CSF cytologic CRs and a 43% rate of overall CRs in the CSF and/or brain parenchyma. Direct injection of rituximab monotherapy (during the first treatment each week) or in combination with methotrexate (during the second treatment each week) was associated with responses in both recurrent leptomeningeal and subependymal disease.

Immunotherapy Agents

In a study using nivolumab, a PD-1 immune checkpoint inhibitor, all five patients responded with four CRs and one PR (four relapsed/refractory PCNSL and one CNS relapse of primary testicular lymphoma), with the caveat that two patients received radiation immediately prior to nivolumab.[323,327] A small retrospective study[309] of six patients assessed the combination of PD-1 checkpoint inhibition, using either pembrolizumab or nivolumab, and rituximab, which showed a 50% response rate, all of which being in CR, durable for at least 7 months.

Adoptive Immunotherapy

Chimeric antigen receptor T (CAR T) cell therapy is another promising therapy.[328] Presently, limited studies analyzing the clinical efficiency of anti-CD19 CAR-T cells in patients with primary or secondary CNS lymphoma are available.[329–331] One study by Li et al.[332] used dual targets against CD19 and CD22. In 2017, a first case report on lisocabtagene maraleucel efficacy in secondary CNS lymphoma was published, showing activity in a patient with secondary CNS involvement of refractory systemic DLBCL.[329] Subsequently, Frigault et al.[330] treated and reported on a retrospective cohort of 8 patients with secondary CNS involvement of the brain, spine, and leptomeninges. Response assessment on day 28 after tisagenlecleucel showed CR in 2 patients, PR in 2 patients, and PD in 4 patients (including two fatalities due to PD). Further follow-up on day 90 revealed ongoing disease control in three of four patients who initially responded to CAR-T cells, and long-term follow-up on day 180 was available in one of those patients showing CR. In the study by Li et al.,[332] two of five patients achieved CR and the other three, PR. Four patients had PD after remission. In addition, one CR patient and one PD patient accepted CAR-T cell infusion following HCT in the third month and were in ongoing remission for 14 and 6 months of follow-up, respectively. Several clinical trials are underway in this area as well (reviewed in detail in Karschnia et al.[328]).

Allogeneic Hematopoietic Stem Cell Transplantation

The intent of therapy in relapsed disease, especially after auto-HCT, is rarely curative.[317,333] Perhaps selected patients in this high-risk group may be considered for allogeneic HCT. Small case reports do hint (not definitively) toward a graft-versus-lymphoma (GvL) effect in the CNS compartment.[334–338] For example, Varadi et al.[337] observed continuous PCNSL shrinkage in parallel to an overt graft-versus-host disease (GvHD) following a nonmyeloablative preparative regimen. In a recent retrospective analysis by Mika et al.,[338] six patients with PCNSL were treated with a myeloablative regimen, five of whom were early relapses, and none of them had prior WBRT. The mean PFS after first-line therapy was only 8.3 months, and four of six patients relapsed within 12 months, indicating highly aggressive disease. All patients were in CRu prior to allo-HCT hence direct assessment GvL effect was not feasible. Overall, four of six patients are alive without further evidence of PCNSL at a minimum of 3.75 years.

Salvage Radiation Therapy

Salvage WBRT may be a reasonable option for radiation, especially for naïve patients who are too frail to receive any other therapy. In a study by Nguyen et al.[339] (n = 27), WBRT (median dose, 36 Gy) resulted in a median estimated survival of 10.9 months (range, 0.3 to 63.7 months). In another study by Hottinger et al.[340] (n = 48), WBRT achieved PR in 21%, SD in 6%, and 15% progress. The median survival from the initiation of WBRT was 16 months. The median time to PCNSL progression was 10 months; 15 patients (31%) had no subsequent disease recurrence after WBRT. Treatment-related neurotoxicity was observed in 22% of patients. Patients older than 60 years and those treated less than 6 months after HD-MTX therapy were at an increased risk of the development of neurotoxicity.

Salvage Stereotactic Radiosurgery

Palmer et al.[341] performed a literature review on the use of stereotactic radiosurgery (SRS) in refractory or recurrent lesions in PCNSL, along with a report of their six patients treated with SRS. They found 16 small series, of which only 1 was prospective and included a control group. Mostly single doses from 12 to 21 Gy were used. As a result, 183 out of 256 evaluated lesions (69%) responded completely to treatment, and in 13 of 204 of the patients (6%), lesions recurred within the treatment area at last follow-up. Overall, the treatment was well tolerated. Additional data is warranted.

PREVENTION OF CNS RELAPSE FOR AGGRESSIVE SYSTEMIC LYMPHOMAS AND CONTROVERSIES

Central Nervous System International Prognostic Index

Even in rituximab era, CNS relapse is an important concern in the subset of patients with systemic high-grade DLBCL and grade 3 B follicular lymphoma. It must be noted that the role of CNS-directed prophylaxis is controversial in the absence of randomized controlled trials. Median OS after CNS relapse is usually short and is in the order of less than 12 months.[342–346] For this reason, it is best to prevent such complications after the recognition of a high-risk population. The CNS IPI model[345] estimates the risk of CNS relapse/progression in patients (18 to 80 years old) with aggressive B-cell lymphomas (80% were DLBCL) who were treated with R-CHOP-like chemotherapy ($n = 2{,}164$) . The factors that contribute significantly to the risk of CNS relapse include age above 60 years, LDH higher than normal range, ECOG PS greater than 1, Ann Arbor stage III or IV, greater than 1 extranodal disease site, or involvement of the kidney or adrenal gland. If present, each factor is given one point. Based on the total number of points, patients are characterized into low- (0 to 1 points), intermediate- (2 to 3 points), or high- (4 to 6 points) risk groups. The respective 2-year rates for the development of CNS disease are 0.6% (95% CI, 0% to 1.2%), 3.4% (95% CI, 2.2% to 4.4%), and 10.2% (95% CI, 6.3% to 14.1%) for low-, intermediate- and high-risk groups, respectively. The resulting risk model was validated in an independent dataset of 1,597 patients with DLBCL identified in the British Columbia Cancer Agency (BCCA) Lymphoid Cancer database. Patients from the validation BCCA dataset showed similar rates of CNS disease for low-risk (0.8%; 95% CI, 0.0% to 1.6%), intermediate-risk (3.9%; 95% CI, 2.3% to 5.5%), and high-risk (12.0%; 95% CI, 7.9% to 16.1%) groups. Close to 90% of patients with DLBCL belong to the low- and intermediate-risk groups and have a CNS relapse risk of less than 5%; they may be spared CNS-directed diagnostic and therapeutic intervention. In contrast, those in the high-risk group have a greater than 10% risk of CNS relapse and may be considered for CNS-directed investigations and prophylactic interventions.

Controversies

A study, by Gleeson et al.[346] called into question the benefit of using prophylactic IT chemotherapy or intravenous HD-MTX, although small numbers in some individual groups limits interpretation. Interestingly, two recent studies by Eyre et al. noted that (i) stand-alone IT CNS prophylaxis provides unclear benefit in reducing the CNS relapse risk in elderly DLBCL patients treated with R-CHOP and is associated with increased infection-related toxicity,[347] and (ii) there are no convincing published data between the period 01/2002 and 01/2019, adjusted for well-described confounding variables, that clearly suggest that stand-alone IT chemotherapy CNS prophylaxis reduces the risk of CNS relapse in patients treated with anthracycline-based front-line immunochemotherapy using an anti-CD20 antibody.[348] It must also be recognized, however, that no individual study provides strong evidence for the lack of benefit of stand-alone IT prophylaxis.[348] Dual expression of MYC and BCL2 (double expressor) by IHC is a high-risk group for CNS disease and relapse and should be considered for CNS-directed evaluation and prophylaxis.[349]

Group With Highest Risk for CNS Disease and in Need of Prophylactic CNS-Directed Therapy

Studies have demonstrated that patients with testicular involvement,[350] double-hit lymphoma (DHT),[351] and intravascular DLBCL,[352] portend the highest risk of CNS disease and relapse. Therefore these patients might derive the most benefit from CNS-directed prophylactic therapy (see Chapter 85).

Preventive Interventions

The use of IT chemotherapy and HD-MTX during or after R-CHOP therapy are the two most commonly used approaches. There are no prospective clinical trials to address the choice of CNS prophylaxis. An international phase II IELSG 10 study[353] showed that R-CHOP with 4 doses of IT methotrexate decreased the rate of CNS relapse, compared with historical controls,[350] in 50 patients with primary testicular DLBCL. In a retrospective series of 95 patients with high-risk (defined as IPI ≥3, elevated LDH, and more than one extranodal site or specific extranodal sites being sinus, epidural, testicular, and breast) DLBCL and grade 3B FL, the use of HD-MTX led to a significantly lower rate of CNS relapse of 5%, compared to the 26% in patients who did not receive CNS prophylaxis.[342] Concerns also exist regarding inability of IT therapy to prevent parenchymal relapses. Therefore systemic therapy with HD-MTX is increasingly used with two different approaches. One approach is to interpose HD-MTX with R-CHOP, to ensure early CNS prophylaxis. A second approach is to deliver HD-MTX after 6 cycles of R-CHOP. A recent multicenter retrospective study compared these two approaches ($n = 204$ interposed vs. $n = 130$ at the end of therapy).[354] The group which received HD-MTX interposed with R-CHOP had delays in systemic therapy that were directly related to HD-MTX. The rate of CNS relapse was 5.7% for the entire group and there were no significant differences in the rate of CNS relapse between the 2 cohorts.

PERSPECTIVE AND FUTURE DIRECTIONS

PCNSL is a challenging disease to study. In this chapter, we have extensively highlighted almost every aspect of DLBCL of the CNS, along with the current challenges, controversies, trials, and future perspectives. Where appropriate, we have also provided our current practice patterns and opinions. As noted, the progress in PCNSL compared to systemic DLBCL has been arduous, and hampered by numerous factors. Improvement in the understanding of genomic landscape has provided rationale for a few precision-based approaches. Investigations are also underway to identify novel diagnostic, predictive, and prognostic biomarkers. New concepts are being explored to prevent iatrogenic encephalopathy. Advances in the field of cellular therapy for PCNSL are also promising.[328,329,338,355] In parallel with the ongoing experimental and clinical advances, it is equally important to further consolidate the global collaborative efforts.

ACKNOWLEDGMENTS

We extend our gratitude toward Arjun G. Patel, PharmD, BCOP (CTCA/affiliate of City of Hope), for diligent review of the tables' accuracy and Thomas Schiera for artwork assistance.

In memory of Dr. Alex Feldman (1984–2022), who was a delightful colleague and an excellent pathologist.

CHAPTER 85

HIGH-GRADE B-CELL LYMPHOMAS

Kieron Dunleavy and Stephen Douglas Smith

High-grade lymphomas are aggressive hematopoietic malignancies derived predominantly from transformed B cells. Notable subtypes include diffuse large B-cell lymphoma (DLBCL), high-grade B-cell lymphoma with MYC and BCL2 and/or BCL6 rearrangements (HGBCL), and Burkitt lymphoma (BL). Although these entities share many clinical and biologic features, the approach to their management is different; therefore an accurate histologic diagnosis is of utmost importance. There have been several recent therapeutic advances in the management of these diseases, and treatment is curative in a large proportion of patients. As a result, prompt diagnosis, evaluation, and institution of appropriate therapy are imperative.

DIFFUSE LARGE B-CELL LYMPHOMA

Epidemiology

DLBCL is the most prevalent histologic subtype of non-Hodgkin lymphoma (NHL) (of which there are approximately 77,000 new cases per year in the United States) and comprises 30% to 40% of all NHL. Although the median age at diagnosis is in the seventh decade of life, DLBCL affects children and adults of all ages, and it is slightly more common in males than females. Although the etiology of DLBCL is unknown in most cases, it can arise from transformation of an indolent lymphoma. A history of immunodeficiency is a significant risk factor, and individuals who are human immunodeficiency virus (HIV) positive have a much higher incidence of DLBCL compared with those who do not have HIV.

Pathobiology

The pathobiology of DLBCL is heterogeneous, and within DLBCL, there are several morphologic variants that include centroblastic, immunoblastic, T-cell rich or histiocyte-rich (see E-Slide VM03959), and anaplastic subtypes. Progress using techniques such as molecular profiling and other high-resolution genomic technologies are further advancing this taxonomy. There are also several clinical-pathologic variants of DLBCL. Primary mediastinal B-cell lymphoma (PMBL), for example, commonly presents in young females and frequently remains localized to the mediastinum (Fig. 85.1). Primary central nervous system lymphoma (PCNSL) is another rare subtype of DLBCL that rarely disseminates to extraneural sites and is observed with higher frequency in HIV-positive individuals (see Chapter 84). It is important to recognize that DLBCL can also arise as a result of histologic transformation from an indolent lymphoma. Although this differentiation may not affect treatment choice initially, it may impact natural history and prognosis of the lymphoma and therefore needs to be recognized at diagnosis.

The neoplastic cells of DLBCL express pan B-cell markers, including CD20, and surface or cytoplasmic immunoglobulin is often demonstrated. CD10, BCL6, and IRF4/MUM1 are variably expressed, and the proliferation index as measured by Ki67 staining is typically high in the range of 70% to 90%. Approximately 30% of cases show abnormalities involving the *BCL6* gene, and translocation of the *BCL2* gene, a hallmark of follicular lymphoma, is present in 20% to 30% of cases. Approximately 10% of cases of DLBCL harbor a t(8:14) *MYC* translocation, which also characterizes BL. The presence of certain translocation combinations has been associated with inferior outcomes following standard therapies. In particular, a new entity called "high-grade B-cell lymphoma with *MYC* and *BCL2* and/or *BCL6* translocations" (HGBCL; colloquially "double hit" lymphoma) has been defined.[1]

Gene expression profiling has defined a new molecular taxonomy for DLBCL. This is continuously evolving as molecular insights into B-cell lymphoma biology become more refined. Morphologically indistinguishable tumors can show marked heterogeneity in gene expression, and these patterns of expression may be classified into signatures that correspond to the cellular origin of the lymphoma according to its stage of B-cell differentiation; on the basis of these signatures, most cases of DLBCL can be divided into a germinal center B-cell (GCB)-like or activated B-cell (ABC)-like subtype. Recently, the identification of genetic heterogeneity within these subtypes has led to further molecular subclassifications.[2,3] Molecular subclassifications of DLBCL are important in that they may define diseases with disparate outcomes and permit development of therapeutic approaches rooted in disease biology, which address the heterogeneity of DLBCL.

Clinical Features

The clinical presentation of DLBCL is variable and depends on a number of factors, including histology, patient age, and immune status. The disease typically presents with lymphadenopathy that can range from relatively asymptomatic to causing pain (Fig. 85.2), causing organ compromise such as ureteral obstruction or spinal cord compression. The involvement of bone marrow (BM) is much less frequent than with indolent lymphomas and is present in approximately 20% of cases.

Patients may have constitutional manifestations from the production of inflammatory molecules and a variety of other cytokines and chemokines produced by the lymphoma cells or host tissues. Such manifestations include weight loss, malaise, fevers, night sweats, and loss of appetite. Of these, unexplained weight loss of more than 10% of body weight, temperature higher than 38° C, and drenching night sweats are referred to as "B symptoms."

Investigation

History and Physical Examination

Patients should be questioned about systemic symptoms, and their performance status should be assessed (Table 85.1). It is important to determine if there is a history of potential causative factors such as prior malignancy, chemotherapy or radiation treatment, or autoimmune or immunodeficiency diseases. A history of infection with or exposure to various pathogens, including HIV and hepatitis B and C, should be excluded. A detailed physical examination should be performed with particular attention to lymph node (LN) regions. Skin involvement by DLBCL is rare but may consist of violaceous papules or larger masses (Fig. 85.3).

An accurate histologic diagnosis is imperative to determine the patient's prognosis and treatment; therefore the single most important diagnostic test is a technically adequate and properly evaluated tissue biopsy—optimally an excisional surgical biopsy. Although core needle biopsy may suffice in some cases, tissue may be inadequate to assess nodal architecture or perform ancillary studies, leading to delay in definitive diagnosis and subclassification. With few exceptions, fine-needle aspiration is inadequate for diagnosis. Aggressive lymphoma should be diagnosed by an experienced hematopathologist familiar with the nuances and pitfalls of lymphoma diagnosis.

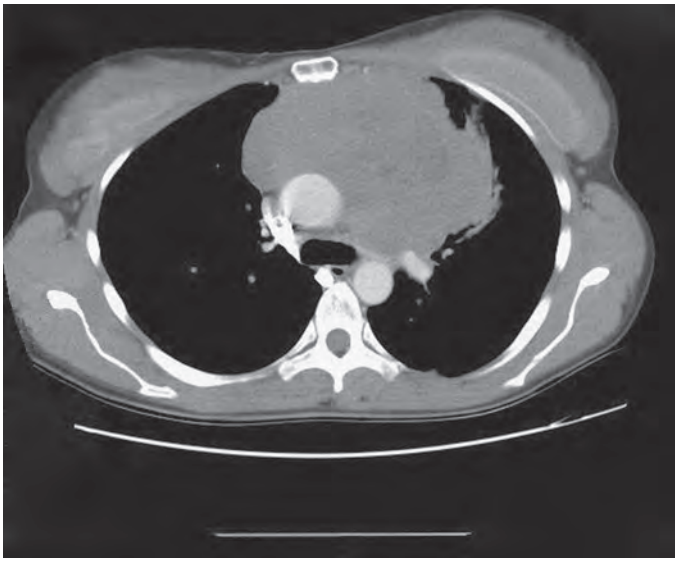

Figure 85.1 COMPUTED TOMOGRAPHY SCAN OF THE CHEST SHOWING A LARGE 17-CM ANTERIOR MEDIASTINAL MASS. A biopsy was consistent with primary mediastinal B-cell lymphoma.

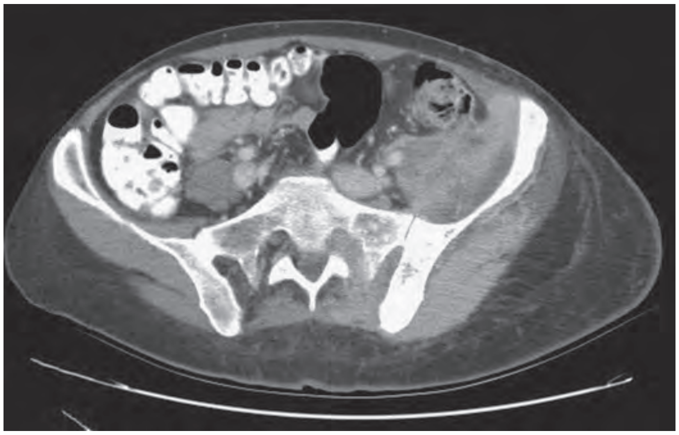

Figure 85.2 COMPUTED TOMOGRAPHY SCAN OF THE ABDOMEN SHOWING A LARGE LEFT-SIDED PSOAS MASS. A biopsy was consistent with diffuse large B-cell lymphoma.

TABLE 85.1 **Eastern Cooperative Oncology Group Performance Scale**

Performance Status	Definition
0	Asymptomatic
1	Symptomatic but fully ambulatory
2	Symptomatic and in bed <50% of the day
3	Symptomatic and in bed >50% of the day
4	Bedridden

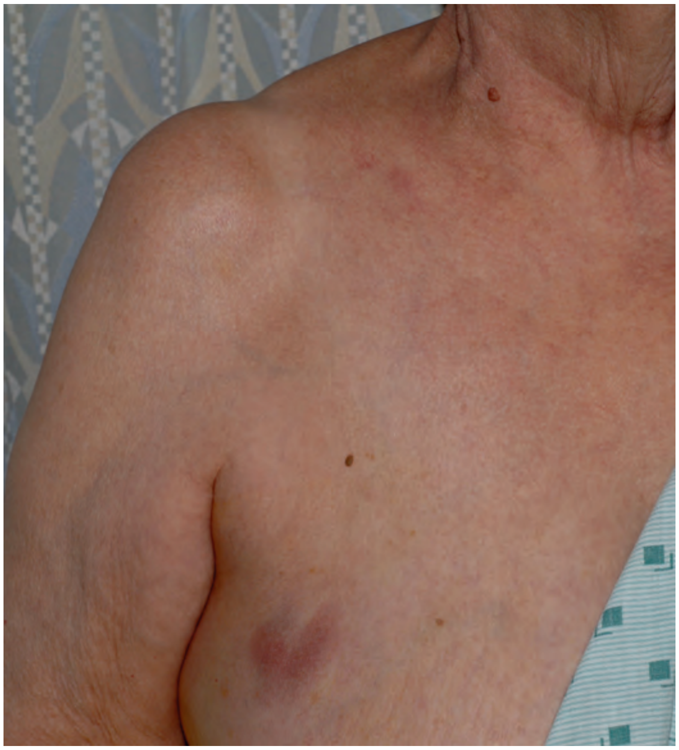

Figure 85.3 INFILTRATION OF THE RIGHT LOWER ANTERIOR CHEST WALL WITH DIFFUSE LARGE B-CELL LYMPHOMA.

Laboratory Investigations

Laboratory tests should include a complete blood count; serum chemistry, including lactate dehydrogenase (LDH); and HIV and hepatitis serology tests (Table 85.2). The latter should be included due to the importance of identifying patients with active hepatitis and a history of hepatitis B, because they will likely require treatment with antivirals, viral load monitoring, or both (see box on Hepatitis B Prophylaxis and Therapy During Lymphoma Treatment). Epstein-Barr virus (EBV) viral loads may also be useful in specific lymphomas such as posttransplant lymphoproliferative disorders (PTLDs) and certain types of EBV-positive DLBCL. An elevated LDH level has adverse prognostic implications for patients with DLBCL.

TABLE 85.2 **Staging Evaluation for Diffuse Large B-Cell Lymphoma**

All Patients	As Clinically Indicated
History and physical examination	CT or MRI of head
CBC and chemistry (including LDH)	Other additional imaging
HIV and hepatitis B and C serology	CSF evaluation by cytology or flow cytometry
CT scan of chest, abdomen and pelvis	Upper endoscopy or colonoscopy
Body FDG-PET scan	Other tests indicated by results of staging
BM aspirate and biopsy	

BM, Bone marrow; *CBC*, complete blood count; *CSF*, cerebrospinal fluid; *CT*, computed tomography; *FDG*, fluorodeoxyglucose; *HIV*, human immunodeficiency virus; *LDH*, lactate dehydrogenase; *MRI*, magnetic resonance imaging; *PET*, positron emission tomography.

HEPATITIS B PROPHYLAXIS AND THERAPY DURING LYMPHOMA TREATMENT

There is a risk of hepatitis B reactivation both from chemotherapy and rituximab, and this is a potentially fatal complication. We check hepatitis serology (hepatitis B surface antigen [HBsAg], hepatitis B surface antibody [anti-HBs], and hepatitis B core antibody [anti-HBc]) in all patients at the time of lymphoma diagnosis. Patients with active hepatitis B receive antiviral medication, and liver function tests (LFTs) and hepatitis B viral loads are monitored closely. Patients with a history of hepatitis B infection (anti-HBc positive but HBsAg negative) should either receive antiviral prophylaxis or have the hepatitis B viral load closely monitored with a low threshold to commence antiviral medications.

Imaging and Staging

It is important to determine sites of disease involvement; therefore imaging studies should include imaging, ideally incorporating fluorodeoxyglucose positron emission tomography (FDG-PET) scanning which is more sensitive than contrast-enhanced computed tomography (CT), particularly for detecting extranodal disease. The use of other imaging modalities depends on the clinical presentation and sites of disease. For example, if central nervous system (CNS) involvement is highly suspected, evaluation of the head by magnetic resonance imaging (MRI) and diagnostic lumbar puncture with flow cytometry may be indicated. Involvement of the bone is best evaluated by PET scans or MRI scans in particular clinical scenarios.

When involvement of the BM may impact management, it should be assessed with DLBCL by a BM aspirate and biopsy, although FDG-PET may detect DLBCL marrow involvement in most cases. Patients at increased risk of CNS involvement should undergo lumbar puncture with evaluation of the cerebrospinal fluid (CSF) by cytology and flow cytometry.[4] Specifically, certain clinical presentations with several extranodal sites and elevated LDH level, as well as particular sites such as the testis, kidney/adrenal gland, breast, and BM, are associated with an increased risk of CNS disease. In high-risk patients, CNS evaluation and prophylaxis should be considered (see box on Central Nervous System Prophylaxis in Diffuse Large B-Cell Lymphoma).

DLBCL is staged according to the Ann Arbor staging system (Table 85.3), which was originally developed for Hodgkin lymphoma (HL). However, because of the heterogeneity and hematogenous pattern of dissemination in NHL, in contrast to contiguous LN spread with HL, the staging system has more limited value. At the same time, important modifications to the Ann Arbor staging system made at the Cotswold Conference have made it more applicable to NHL.

TABLE 85.3 **Ann Arbor Staging System for Lymphomas**

Stage[a]	Cotswold Modification of Arbor Classification
I	Involvement of a single LN region or lymphoid structure
II	Involvement of two or more LN regions on the same side of the diaphragm (the mediastinum is considered a single site, but the hilar LNs are considered bilaterally); the number of atomic sites should be indicated by a subscript (e.g., II_3)
III	Involvement of LN regions on both sides of the diaphragm: III_1 (with or without involvement of splenic hilar, celiac, or portal nodes) and III_2 (with involvement of paraaortic, iliac, and mesenteric nodes)
IV	Involvement of one or more extranodal sites in addition to a site for which the designation E has been used

[a] All cases are subclassified to indicate the absence (A) or presence (B) of the systemic symptoms of significant fever (>38.0°C [100.4(F]), night sweats, and unexplained weight loss exceeding 10% of normal body weight within the previous 6 months. The clinical stage (CS) denotes the stage as determined by all diagnostic examinations and a single diagnostic biopsy only. In the Ann Arbor classification, the term *pathologic stage* (PS) is used if a second biopsy of any kind has been obtained, whether the result was negative or positive. In the Cotswold modification, the PS is determined by laparotomy; X designates bulky disease (widening of the mediastinum by more than one-third or the presence of a nodal mass >10 cm), and E designates involvement of a single extranodal site that is contiguous or proximal to the known nodal site.
LN, Lymph node.

CENTRAL NERVOUS SYSTEM PROPHYLAXIS IN DIFFUSE LARGE B-CELL LYMPHOMA

In DLBCL, the role of central nervous system (CNS) prophylaxis to prevent CNS recurrence is controversial, and several different approaches are followed. There is not widespread agreement on which patients should receive prophylaxis—the CNS International Prognostic Index (CNS-IPI) has been helpful in this respect. All patients at high risk (score 4–6) for CNS involvement undergo a lumbar puncture at diagnosis, and CSF is checked by cytology and flow cytometry; if the results are positive, patients receive active treatment of the CNS. If results are negative, consideration of prophylaxis using intrathecal and/or intravenous chemotherapy is required, although data are unclear on the optimal agent, route, dose, and duration of such therapy. If the results are negative, we strongly consider the use of prophylaxis in high-risk patients, particularly those with more than one extranodal disease site. In addition, certain extranodal locations such as the testis or bone marrow are considered to be associated with a high risk of CNS dissemination, and CNS prophylaxis should be considered.

The type and dosing schedule of CNS prophylaxis is controversial because prospective data are lacking. We frequently use intrathecal methotrexate at a dose of 12 mg. Prophylaxis is started on cycle 3 for a total of 4 cycles. The reason for delaying institution of prophylaxis is to avoid potential increased toxicity from immunochemotherapy in the early cycles. (See Chapter 84.)

Prognosis

To identify prognostic factors in NHL, an international project to correlate clinical variables and outcome in 2031 patients with untreated aggressive lymphoma was undertaken. The following parameters were associated with inferior outcome: age older than 60 years, Ann Arbor stage III or IV disease, serum LDH level above normal range, Eastern Cooperative Oncology Group (ECOG) performance status of two or higher, and involvement of two or more extranodal sites. A clinical prognostic model, termed the International Prognostic Index (IPI), was developed using these five factors. In this model, one point was allocated for each feature and nicely stratified patients into four groups with 5-year survivals of 73%, 51%, 43%, and 26% for zero or one, two, three, and four or five risk factors, respectively, with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP)-based treatment. Based on this model, the IPI has become the standard in DLBCL for assessing clinical prognosis and treatment stratification within and comparison between clinical trials. A revised prognostic model for R-CHOP, termed the *Revised-IPI*, was also developed (Table 85.4).[5]

Although not yet routinely performed in high-grade B-cell lymphoma, gene expression profiling with assessment of tumor genomic characteristics is emerging as an important prognostic tool. In many studies in DLBCL, outcome following standard therapy has been superior in patients with the GCB compared with the ABC subtype (Fig. 85.4). In routine clinical practice, it has not been feasible to perform gene expression profiling or complex mutational assays and immunohistochemistry algorithms (e.g., Hans algorithm) to predict cell of origin have been applied. Although these are helpful, they have demonstrated varying degrees of concordance with microarray results, limiting their usefulness. Alternative assays to more accurately predict cell of origin are needed, and many studies are investigating limited gene predictor assays.[6] Similarly, DLBCL with simultaneous MYC and BCL2 protein overexpression by immunohistochemistry is associated with inferior outcomes, but reproducibility of IHC in this setting is a concern.[7]

TABLE 85.4 Revised International Prognostic Index[a]

No. of IPI Factors	IPI Score	Outcome	Overall Survival (%)
0	0	Very good	94
1–2	1–2	Good	79
3, 4, or 5	3–5	Poor	55

[a] One point is given for the presence of each of the following characteristics: age older than 60 years, elevated serum LDH level, ECOG performance status 2, Ann Arbor stage III or IV, and more than two extranodal sites.

ECOG, Eastern Cooperative Oncology Group; *IPI*, International Prognostic Index; *LDH*, lactate dehydrogenase.

From Sehn LH, Berry B, Chhanabhai M, et al. The revised International Prognostic Index (R-IPI) is a better predictor of outcome than the standard IPI for patients with diffuse large B-cell lymphoma treated with R-CHOP. *Blood.* 2007;109:1857.

Improved elucidation of the heterogeneous biology of DLBCL has led to the investigation of strategies and novel agents that have selective activity within molecular subtypes and sets the stage for a future era of precision medicine in front-line DLBCL therapeutics, where therapy could be ascribed based on molecular characteristics. Recent molecular classifications of DLBCL have relied significantly on the presence or absence of distinct mutations within cell of origin subtypes, and many of these mutations are “targetable” with small molecule inhibitors.

Treatment

The mainstay of treatment for DLBCL is systemic chemotherapy; radiation treatment alone is inadequate and associated with high recurrence rates. For early-stage disease, whether or not radiation treatment adds benefit to chemotherapy has been controversial. Based on a randomized study that showed a survival advantage of limited course CHOP plus involved field radiation compared with full-course CHOP in early stage (I/II) aggressive lymphoma, combined modality therapy became the standard. However, longer patient follow-up showed a convergence of the overall survival (OS) curves because of late systemic relapses in the combined modality arm, necessitating further trials conducted in the modern R-CHOP era to clarify the role of radiation. Recently, a series of prospective trials in early-stage DLBCL without bulky adenopathy has shown consistently excellent outcomes using four to six cycles of R-CHOP without radiation therapy.[8–10] These trials demonstrate that early-stage patients lacking high-risk features by the IPI, bulk, or achieving FDG-PET negativity after 3 cycles of R-CHOP may be treated with 4 cycles of chemotherapy alone. Additional R-CHOP (to 6 cycles) or incorporation of radiation therapy remains a reasonable strategy in select patients, based on baseline disease risk and anticipated or observed tolerance of therapy.

Patients with advanced-stage DLBCL typically receive 6 cycles of rituximab in combination with CHOP chemotherapy.[11] This backbone has been used since the early 1970s, when doxorubicin was added to cyclophosphamide, vincristine, and prednisone (CVP) and CHOP became the first curative regimen in DLBCL, highlighting the critical role of anthracyclines. Later on, in an attempt to improve upon the results with CHOP, studies focused on the empiric addition of drugs to the regimen. However, this did not improve survival but increased toxicity. The addition of rituximab to CHOP by the GELA group (Groupe d’Etude des Lymphomes de l’Adulte) 20 years ago demonstrated a significant survival advantage in elderly patients with DLBCL, and this advantage was also demonstrated in young patients (younger than the age of 60 years), leading to its acceptance as the standard first-line approach currently. Due to promising activity in single-arm trials in DLBCL, DA-EPOCH-R (dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, hydroxydaunorubicin, and rituximab) was compared with R-CHOP in a prospective randomized study. The efficacy was similar in both groups, but toxicity was higher in DA-EPOCH-R; this study was not powered to compare outcomes of subsets such as PMBCL and MYC-rearranged DLBCL, where the regimen has demonstrated good activity in single-arm studies. Whether younger patients (more likely to tolerate and benefit from dose escalation inherent to DA-EPOCH-R) or certain biologic subsets (more susceptible to continuous infusion chemotherapy exposure) may benefit remains a matter of active consideration and debate. A small proportion of aggressive B-cell lymphoma cases harbor rearrangements of MYC and BCL2 and/or BCL6—these tumors were previously referred to as “double-hit” or “triple-hit” lymphomas but the World Health Organization (WHO) Lymphoid Classification has put them into a distinct category called “high-grade B-cell lymphoma with rearrangements of MYC and BCL2 and/or BCL6” (Fig.85.5).[1] They are clinically aggressive diseases that have been associated with inferior outcomes compared with DLBCL-NOS (not otherwise specified), and currently, their optimal management has not been defined. High-intensity approaches such as those used in BL are favored by many.[12]

PMBL was once considered to be a subtype of DLBCL but is now considered a distinct clinicopathologic entity. It is approached therapeutically with immunochemotherapy, but this is frequently followed by consolidation mediastinal radiation depending on the regimen used. In early studies with approaches such as the MACOP-B (methotrexate, ARA-C [Cytarabine], cyclophosphamide, vincristine, prednisone, and bleomycin) regimen followed by radiation, 66% of patients had persistently positive gallium scans after chemotherapy, suggesting active disease; however, following consolidation radiotherapy, just 19% had a positive gallium scan, and 80% were event free at 39 months of median follow-up. This study suggested that radiotherapy was necessary after chemotherapy. Although the addition of rituximab to CHOP has improved outcome in DLBCL, there remains a significant proportion of patients with PMBCL who require consolidation radiation. More intensive regimens than R-CHOP, such as dose-adjusted EPOCH-R (DA-EPOCH-R) or R-ACVBP (rituximab, doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone), challenge the need for radiation in PMBL; regarding the use of DA-EPOCH-R, in a prospective study of 53 patients, 93% were event free without radiation (see box on Treatment of Primary Mediastinal B-Cell Lymphoma).[13,14] These results suggest that obviating the need for radiation is possible in this disease with more intensive approaches, thus eliminating the risk of long-term toxicities such as secondary malignancies and heart disease. An ongoing study by the International Extranodal Lymphoma

TREATMENT OF PRIMARY MEDIASTINAL B-CELL LYMPHOMA

Patients with a diagnosis of PMBL undergo routine body CT and/or FDG-PET imaging and staging. We administer six cycles of DA-EPOCH-R. After four cycles of therapy, the CT is repeated, and after six cycles an FDG-PET scan is performed. If patients have responded and the posttherapy PET scan result is negative, surveillance with clinical evaluation including history, physical, and laboratory studies—and in select cases, periodic CT imaging—is initiated. If the FDG-PET result is overtly positive, a biopsy is frequently performed, and if there is residual disease, patients undergo mediastinal radiation treatment or further systemic treatment. If the FDG-PET result is suspicious, which may be due to varied benign causes including thymic rebound, posttreatment inflammatory or infectious lesions, or brown fat uptake in young patients, the FDG-PET scan is repeated at intervals of 6–8 weeks. If at this time, there is evidence of improvement or the scan is negative, patients go into routine follow-up; and if the changes are worsening or remain abnormal, a biopsy is attempted, and salvage therapy initiated if residual disease is proven. In light of complexities around FDG-PET restaging, the variable relapse pattern (which can be local or include extranodal sites), the rarity and young affected age, and a rapidly evolving treatment landscape, thorough restaging and consideration of tertiary care center referral are critical in PMBCL beyond first-line therapy.

CT, Computed tomography; *DA-EPOCH-R*, dose adjusted etoposide, prednisone, vincristine, cyclophosphamide, hydroxydaunorubicin, and rituximab; *FDG-PET*, fluorodeoxyglucose positron emission tomography; *PMBL*, primary mediastinal B-cell lymphoma.

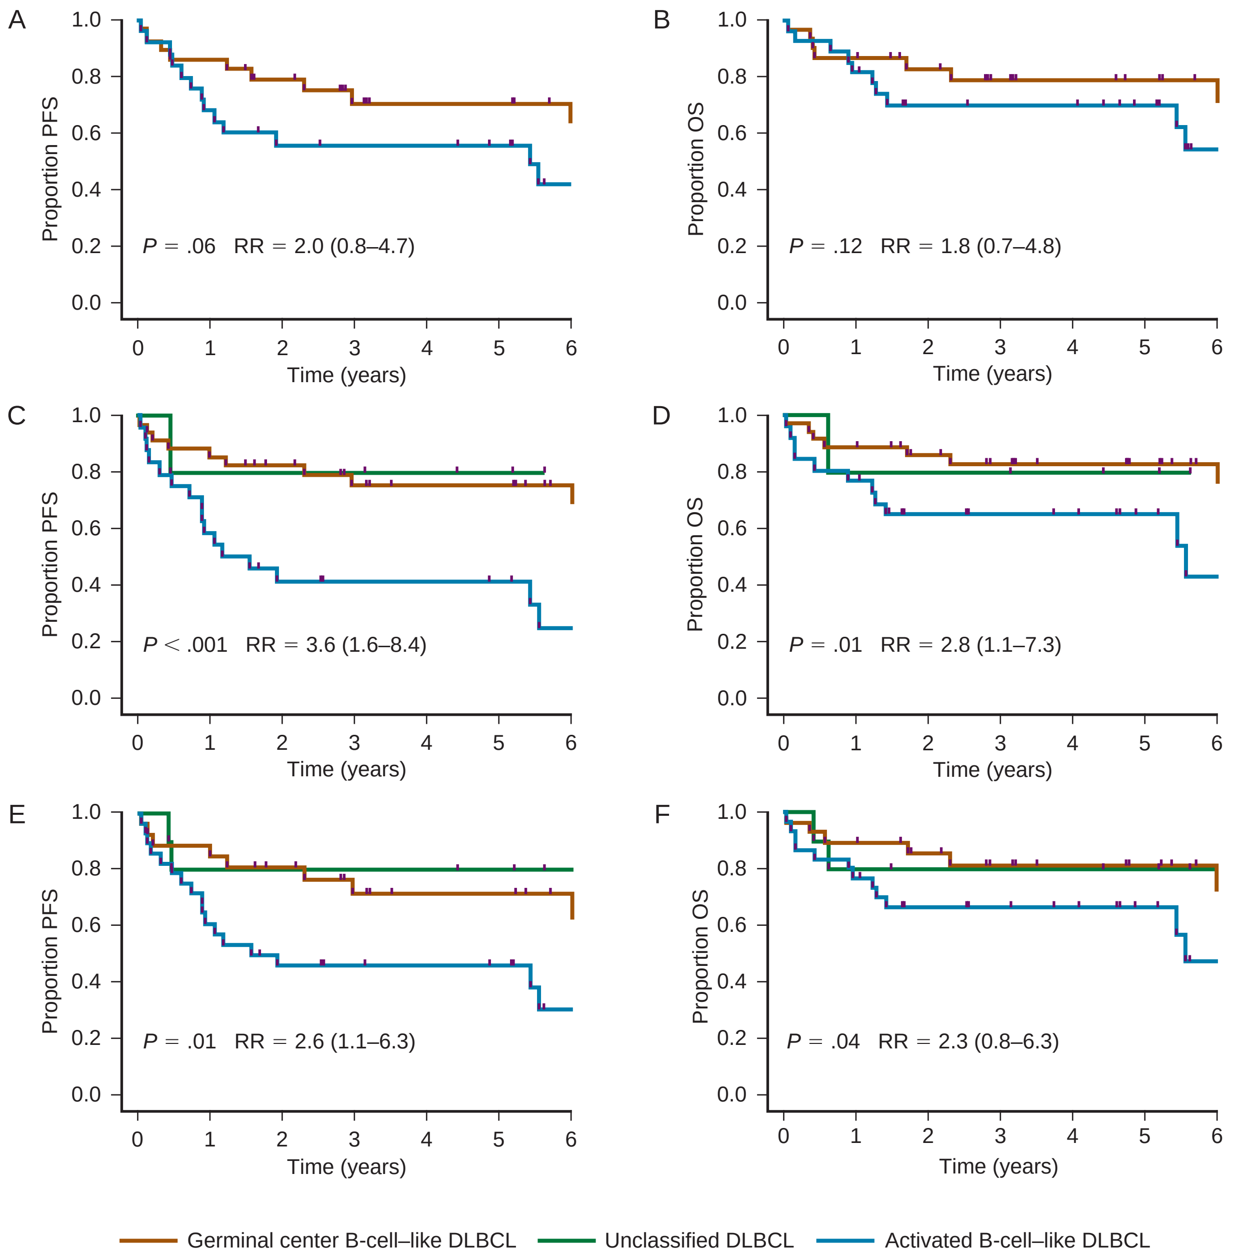

Figure 85.4 PATIENTS WITH DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL) OUTCOMES FOLLOWING R-CHOP ACCORDING TO CELL ORIGIN (COO; IN THE INDEPENDENT VALIDATION COHORT). (A) Progression-free survival (PFS) for COO assignment using the "Hans" algorithm. (B) Overall survival (OS) for COO assignment using the "Hans" algorithm. (C) PFS in the COO groups as determined by the Lymph2Cx assay. (D) OS in the COO groups as determined by the Lymph2Cx assay. (E) PFS in the COO groups determined by the gold standard method applying the previously described model to gene expression on frozen tissue (FT). (F) OS in the COO groups determined by the gold standard method. The *P*-values are from log-rank tests comparing the activated B-cell (ABC) and germinal center B-cell (GCB) groups. The log-rank tests are one sided in the direction of greater hazard for ABC. *RR*, Relative risk (with the 95% confidence interval in brackets) associated with the ABC group compared with the GCB group. *(Republished with permission of the American Society of Hematology from Scott DW, Wright GW, Williams PM, et al. Determining cell-of-origin subtypes of diffuse large B-cell lymphoma using gene expression in formalin-fixed paraffin-embedded tissue. Blood. 2014;123:1214.)*

Study Group (IELSG) is testing if mediastinal radiation can be omitted in patients who have a negative end of therapy (EOT) FDG-PET scan.[15] Clinically and biologically, PMBCL shares many features with classical HL, and in particular, overexpression of programmed death receptor 1/programmed death ligand 1 (PD-1/PD-L1) is commonly found. New approaches such as immune checkpoint inhibitors have demonstrated high activity in HL and are also effective in relapsed/refractory cases of PMBCL and are currently being investigated in the upfront setting.

The appreciation of disease heterogeneity within DLBCL and the existence of subtypes that can be differentially targeted due to distinct oncogenic mechanisms has led to recent novel drug development in the disease. In particular, a number of studies have investigated strategies that target the nuclear factor (NF)-(B pathway in ABC DLBCL. Bruton tyrosine kinase inhibition has demonstrated good but short-lived activity in ABC DLBCL in the relapsed/refractory setting; based on this activity, the recently published PHOENIX study (NCT01855750) compared ibrutinib with R-CHOP to R-CHOP alone, but the addition of ibrutinib was not associated with a better overall outcome.[16] The immunomodulatory agent lenalidomide is also activated in relapsed/refractory ABC-DLBCL, but when lenalidomide was added to R-CHOP, it was not superior to R-CHOP alone in newly diagnosed DLBCL when tested in the ABC subtype or all-comers. Over the past few

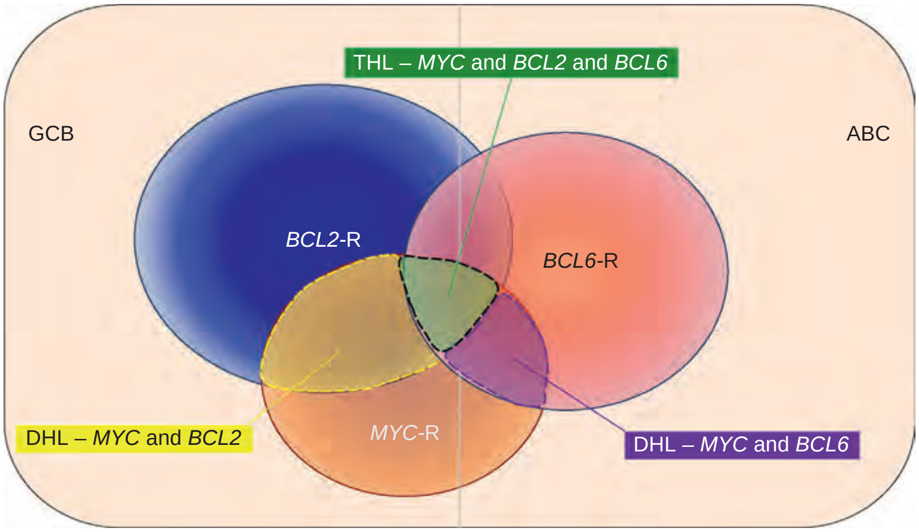

Figure 85.5 GRAPHIC REPRESENTATION OF THE NEW CATEGORY OF AGGRESSIVE B-CELL LYMPHOMAS—"HIGH-GRADE B-CELL LYMPHOMAS WITH MYC AND BCL2 AND/OR BCL6 REARRANGEMENTS." This was described in the 2016 revision to the World Health Organization Classification of Tumors of Hematopoietic and Lymphoid Tumors (2008). Most cases with MYC and BCL2 rearrangements are of germinal center B-cell origin, whereas most cases with BCL6 rearrangements are of activated B-cell origin. This category includes double-hit (DH) lymphomas that involve MYC and BCL2 or MYC and BCL6 and triple hit (TH) lymphomas that involve MYC, BCL2, and BCL6.

decades, there have been significant improvements in the outcome of patients with HIV-associated DLBCL, and these can be attributed to the widespread availability of combination antiretroviral therapy (CART) and to advances in the therapeutics of these diseases. The AIDS Malignancy Consortium in the United States reported excellent results for patients with newly diagnosed aggressive B-cell lymphoma with the DA-EPOCH-R that were similar to survival outcomes in HIV-negative cases.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

PCNSL is a rare and highly aggressive lymphoma confined to the CNS and is of diffuse large B-cell histology in more than 90% of cases. Its unique radiographic findings present challenges in evaluation. The incidence of PCNSL is particularly high in the setting of HIV infection, in which it often presents with multifocal disease and is virtually always associated with EBV. In contrast, PCNSL in HIV-negative patients often presents with solitary intracranial masses and is almost never associated with EBV (Fig. 85.6).

Treatment of PCNSL differs from systemic DLBCL because many chemotherapy agents that are standard for treatment of the latter do not adequately penetrate the blood-brain barrier. Radiotherapy has been a mainstay of treatment because it is effective and sidestepped the limitations of chemotherapy, but responses are usually short lived, and virtually all patients relapse. In contrast, high-dose methotrexate (HD-MTX) is a cytotoxic agent with good CNS penetration, but when used alone, progression-free survival (PFS) is relatively short and prolonged dosing or consolidation are considered. A logical step was to administer HD-MTX followed by whole-brain radiotherapy, and this resulted in high complete response (CR) rates and median PFS rates of 32 to 40 months. Unfortunately, such combined modality treatment is associated with severe long-term neurotoxicity, and recently, a high incidence of late relapses has been identified for this disease entity. For this reason, there has been much interest in developing regimens that obviate or defer the need for radiation until relapse. Many intensive approaches have been investigated, frequently followed by autologous stem-cell transplantation, particularly in younger patients. Interestingly, most DLBCLs that arise in the CNS have biologic features that resemble the systemic ABC subtype and a high proportion have mutations in the B-cell receptor (BCR) and MYD88. Therefore there is interest in pursuing strategies that target BCR signaling as well as using immunomodulatory agents in these diseases.[17] See Chapter 84 for more comprehensive discussion of PCNSL.

BURKITT LYMPHOMA

Epidemiology

BL mostly occurs in the first two decades of life, is more common in males, and accounts for some 2% of all lymphomas. There are

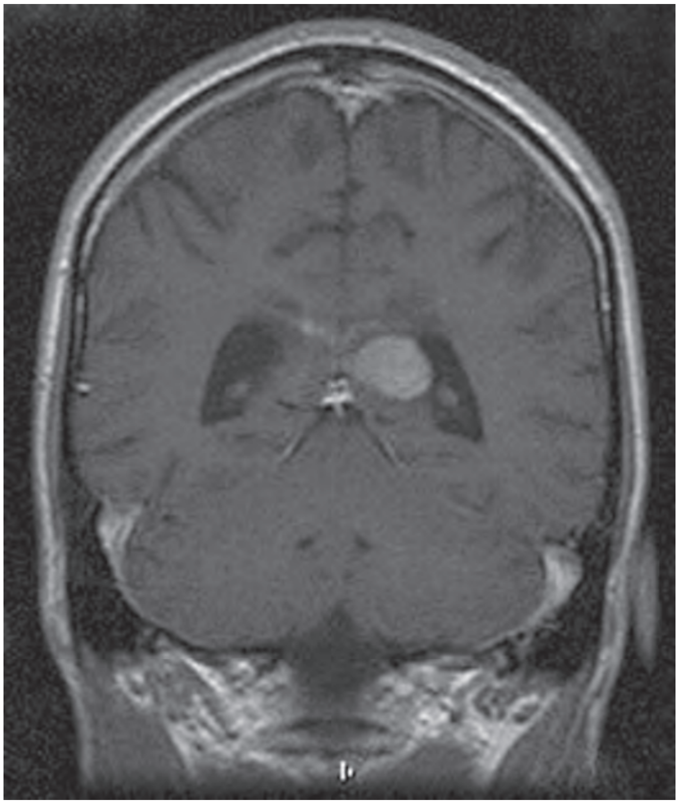

Figure 85.6 THIS GADOLINIUM-ENHANCED MAGNETIC RESONANCE IMAGING SCAN OF THE BRAIN SHOWS AN ENHANCING INFILTRATIVE MASS IN THE MAJOR FORCEPS OF THE CORPUS CALLOSUM. A biopsy was consistent with primary central nervous system lymphoma.

three recognized clinical variants, and they vary in whom they affect and how they present, and they also have morphologic and biologic differences. Endemic BL occurs in equatorial Africa and Papua New Guinea, peaks in incidence in 4- to 7-year-old children, and is predominantly a male disease. Sporadic BL presents worldwide and is the most common variant in the Western world. It typically affects children and young adults and is more commonly observed in boys. Immunodeficiency-associated BL occurs in association with HIV infection and is approximately 1000 times more common in HIV-infected individuals.

Pathobiology

BL is highly aggressive and characterized by an extremely high proliferation rate approaching 100% and a high fraction of apoptosis, and this accounts for its “starry sky” appearance (see E-Slide VM03958). Although a leukemic phase of BL can occur in patients with advanced disease, it is very rare for BL to present purely as acute leukemia. Biologically, BL is derived from a GCB cell as indicated by its CD20$^+$, CD10$^+$, and terminal deoxynucleotidyl transferase (TdT)-negative immunohistochemical profile and gene expression profiling. The neoplastic cells are usually negative or weakly positive for BCL2. Although EBV is virtually always detected in endemic BL, it is only present in 25% to 40% of sporadic and immunodeficiency-associated cases.

Although virtually all cases of BL have MYC translocations, usually at 8q24 to the immunoglobulin heavy chain region, MYC translocations are not specific for BL and can be found in other aggressive B-cell lymphomas (Fig. 85.7). BL has a unique gene expression signature that is molecularly distinct from that of DLBCL. Studies have demonstrated that some cases of DLBCL by histology have gene expression profiles consistent with BL. Given that BL does not respond well to CHOP-based treatments, this distinction by molecular profiling is important, and gene expression profiling may be useful in rare cases that would otherwise be diagnosed as DLBCL. In addition, there are cases with a profile intermediate between that of DLBCL and BL; these cases typically harbor MYC, and most would fall into the new aforementioned category “high-grade B-cell lymphoma with MYC and BCL2 and/or BCL6 translocations.”

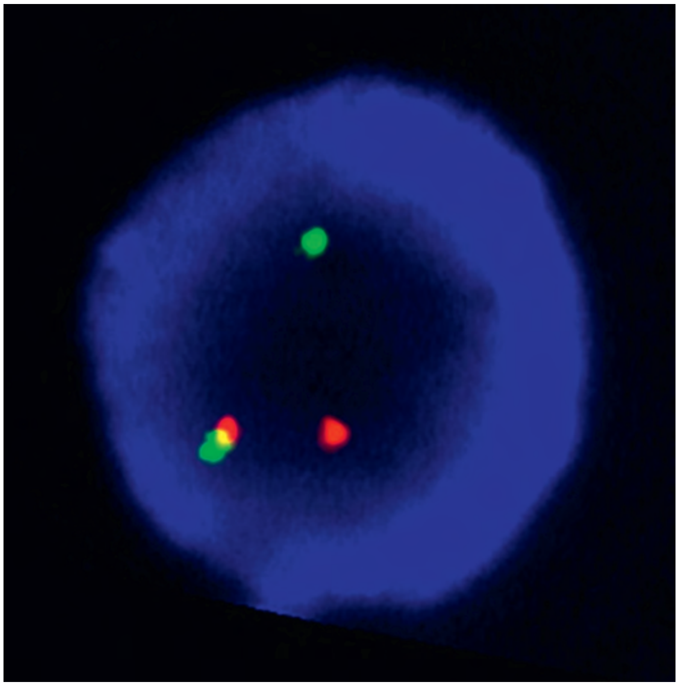

Figure 85.7 FLUORESCENT IN SITU HYBRIDIZATION SHOWING AN MYC TRANSLOCATION IN A PATIENT WITH DIFFUSE LARGE B-CELL LYMPHOMA. This is a break apart probe (LSI-MYC) with one normal (fused) signal and one abnormal (separated green and red) signal indicating a translocation involving MYC.

Clinical Features

The clinical presentation of BL is variable and depends on the epidemiologic subtype as well as other factors. In endemic BL, it is common for patients to present with jaw and other facial disease, and other extranodal sites of involvement include the ileocecum, gonads, kidneys, and breasts. The ileocecal area is the most common site of disease involvement in sporadic BL, and occasionally umbilical involvement can be clinically detected (Fig. 85.8). Jaw involvement is very rare. In immunodeficiency-associated BL, involvement of the ileocecum, LNs, and BM is commonly observed. Patients often present with advanced-stage and bulky disease caused by the short doubling time of the tumor, and it is common for patients to develop tumor lysis syndrome (TLS) after the institution of therapy.

Investigation

History and Physical Examination and Laboratory Investigations

Similar to patients with DLBCL, a detailed history and physical examination are required, and the diagnosis of BL should be made by an experienced hematopathologist. Given its association with HIV infection, it is imperative to perform an HIV test at diagnosis and to check hepatitis serologies.

Imaging and Staging

As with DLBCL, imaging studies should include chest radiography and FDG-PET or CT scanning of the chest, abdomen, and pelvis. The need for additional imaging studies depends on the clinical presentation. A BM aspirate and biopsy should be performed in all patients, and select, high-risk patients should undergo a lumbar puncture with evaluation of the CSF by cytology and flow cytometry. Although BL in adults is staged according to the Ann Arbor staging system, the Murphy staging system is often used in children.

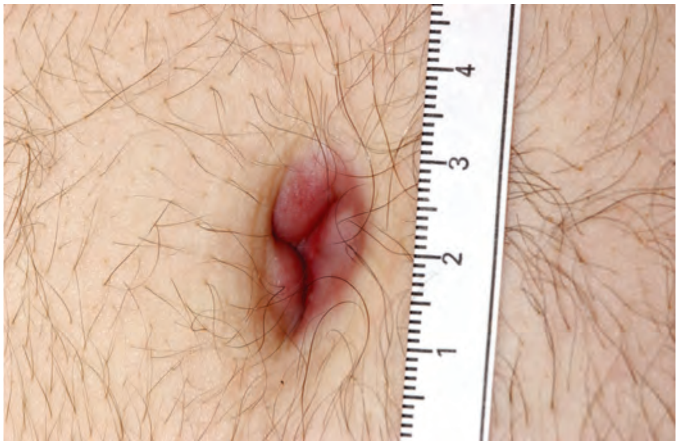

Figure 85.8 BURKITT LYMPHOMA (BL) INVOLVING THE UMBILICUS. This is an 18-year-old man who presented with a history of abdominal pain. Computed tomography scan demonstrated a large intra-abdominal mass extending up to the umbilicus, and a biopsy revealed it to be BL.

Prognosis

Age, large tumor volume, and CNS involvement have been associated with a poor prognosis in the past. Although early studies demonstrated that HIV-positive patients with BL had a worse outcome, this has not been the case with newer treatment approaches. Recently, an analysis of a large cohort of BL patients led to identification of four independent prognostic factors: age 40 years or older, LDH elevation greater than three times the upper limit of normal, ECOG performance status 2 or higher, and CNS involvement; presence of two to four factors (seen in approximately half of BL included patients) comprised the high-risk group, portending a 3-year PFS of approximately 50%.[18]

Treatment

BL is a systemic disease and requires chemotherapy for all disease stages. Importantly, locoregional radiation does not improve survival and should be avoided. Early treatment strategies for BL were modeled on acute lymphoblastic leukemia (ALL) regimens that used dose-intense and prolonged treatment with induction, consolidation, and maintenance phases. Although dose intensity and dose density are important treatment components for BL, later studies indicated that shorter treatment durations were equally effective. Later, risk adaptive approaches allowed further reductions in treatment for patients with early-stage disease. Several biologic characteristics of BL have helped guide treatment strategies, including its high proliferative fraction.

The risks of TLS and propensity for CNS dissemination in BL also have important treatment implications. All patients should receive TLS prophylaxis during the first cycle and undergo close electrolyte monitoring. The high risk of CNS involvement has prompted the use in the past of relatively high-dose intravenous methotrexate and cytarabine, both of which have CNS penetration, as well as intrathecal administration of these drugs. An important advance has been to reduce intrathecal treatment and eliminate whole-brain radiation for prophylaxis, which has significantly reduced CNS toxicity. A study published by the FAB/LMB (French American British/Lymphomes Malins B) group demonstrated that patients with early-stage BL had a high cure rate and very low rate of CNS relapse without the use of intrathecal chemotherapy.[17]

There are multiple highly effective regimens for BL; however, because of the rarity of the disease (there are only 1200 new cases in the United States each year), there are no good comparative studies of different therapies in BL. A variety of dose-intense short-duration regimens have achieved durable CRs in a high proportion of patients. Included in these are the French LMB and German Berlin-Frankfurt-Münster (BFM) protocols and the National Cancer Institute CODOX-M/IVAC (cyclophosphamide, vincristine, doxorubicin, and HD-MTX alternating with ifosfamide, etoposide, and high-dose cytarabine; intrathecal methotrexate and cytarabine are also administered) regimen. These regimens are similar in their drug composition, short cycle length, and CNS prophylaxis. Although most BL occurs in children, Magrath and colleagues demonstrated that adults have a similar disease outcome when treated with the same approaches and reported high cure rates. Other groups have confirmed the efficacy of this regimen, albeit with lower survival rates. In the United Kingdom, Mead and colleagues reported an overall event-free survival (EFS) of 65% at 2 years. The hyper-CVAD (cyclophosphamide, vincristine, doxorubicin, and dexamethasone) regimen has also been tested in BL, with good results (recently with the addition of rituximab). Rituximab is typically used in this disease, and randomized studies in both children and adults demonstrate that it adds a survival advantage.

Toxicity is an important clinical limitation of these regimens in adults, particularly in older patients and in patients who are immunosuppressed, in whom severe morbidity and even mortality occur. Therefore one of the major therapeutic challenges in BL is to develop therapies that are as effective in achieving high cure rates as "standard" regimens but that also improve the therapeutic index and reduce toxicity complications. This approach has been investigated using EPOCH-R–based therapy in BL. The approach was associated with a high PFS of more than 90% in an early study and validated in a multicenter study in low- and high-risk groups.[19] There were low rates of TLS and other toxicities compared with conventional BL regimens. In the setting of HIV infection, a concern with standard BL regimens has been toxicity, and less toxic appear to be more appropriate.

SALVAGE THERAPY

The salvage treatment of relapsed DLBCL should be approached in an individual manner because the choice of treatment is influenced by the time to recurrence, prior therapy, patient's performance status and comorbidities, and the potential for cure. Although most relapsed aggressive lymphomas require combination chemotherapy for adequate disease control, a subset of patients with local disease may be salvaged with radiation therapy. Examples include primary mediastinal DLBCL, which can remain local even at relapse, and PTLDs, which may have an isolated resistant EBV clone after chemotherapy.

A variety of active salvage chemotherapy regimens are available for relapsed or refractory DLBCL. Platinum-containing regimens, such as ESHAP (etoposide, methylprednisolone, cytosine arabinoside, and platinum), DHAP (dexamethasone, cisplatin, cytarabine arabinoside), GDP (gemcitabine, dexamethasone, cisplatin), and ICE (ifosfamide, carboplatin, and etoposide), combined with rituximab are widely used.

Patients with chemotherapy-sensitive disease have the best outcome with autologous stem cell transplant (ASCT), and this is recommended at initial relapse; in the pre-rituximab era, this approach yielded OS and EFS rates in the range of 40% to 50% and 30% to 40%, respectively. However, the improvement in upfront curability of DLBCL because of immunochemotherapy has diminished the efficacy of ASCT at relapse. In addition, recent randomized data suggest that some patients with primary refractory/relapsed DLBCL have improved outcomes with CD19-directed chimeric antigen receptor T cell (CAR-T cell) therapy.[20]

There are a number of novel agents and strategies that have demonstrated good activity in relapsed/refractory DLBCL (Fig. 85.9), and some of these are now being investigated in front-line DLBCL studies. Anti-CD19 CAR-T-cell therapy has led to long-term remissions in a significant proportion of patients with relapsed/refractory disease, and this has led to the US Food and Drug Administration (FDA) approval of anti-CD19 CAR-T-cell therapy in relapsed/refractory DLBCL after two lines of therapy.[21–23] CD19 can additionally be targeted by monoclonal antibodies, and recently one such antibody, tafasitamab, showed adequate activity in combination with lenalidomide to lead to FDA approval in relapsed/refractory DLBCL.[24] Polatuzumab is an antibody-drug conjugate directed against CD79B and based on a randomized study of the drug in combination with bendamustine-rituximab (B-R); it was FDA approved for relapsed/refractory disease.[25] Another strategy that inhibits XP01-mediated nuclear transport nuclear export, selinexor, was also recently FDA approved. Notably, none of these strategies have been compared with one another, and differences in trial populations and nuanced eligibility criteria make application to the clinical setting a challenge. Among newer experimental approaches, antibodies targeting several unique B-cell antigens and others targeting multiple antigens simultaneously (including bispecific T-cell engagers [BITEs]) are being investigated in this DLBCL.

With regard to BL, the outcome for patients who relapse after or progress during initial therapy—which generally is observed within a year of first diagnosis—is extremely poor, and there are no standard approaches that have been associated with good outcomes. Experimental approaches should be strongly considered in this setting.

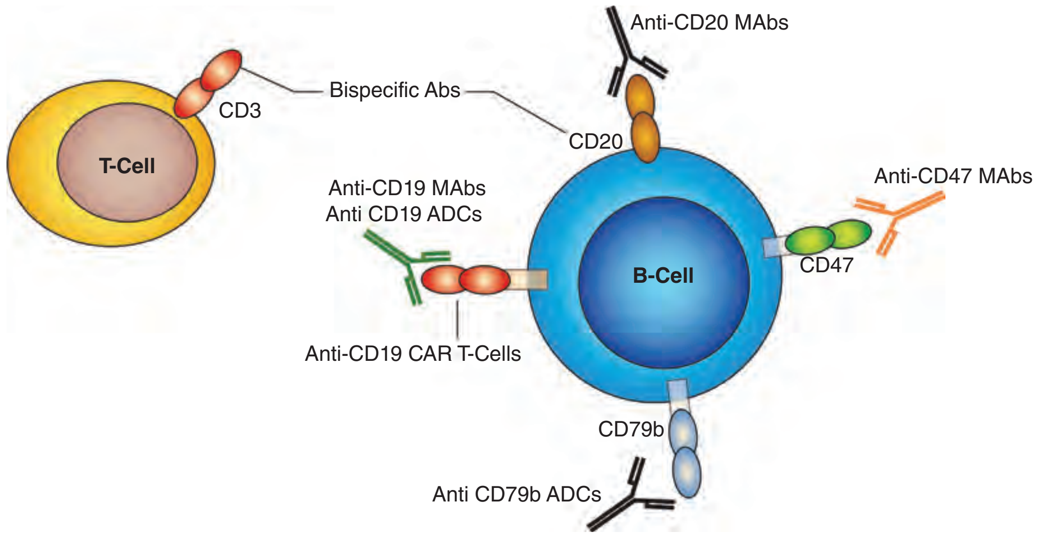

Figure 85.9 SELECT NOVEL TARGETS AND AGENTS IN DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL). Recently, a number of new strategies have been developed to target DLBCL. These include novel monoclonal antibodies and antibody-drug conjugates against CD19, CD79b, and CD47. Anti-chimeric antigen T-cell therapy (CAR-T) has been developed against antigens including CD19 and bispecific antibodies against CD20 (B cells) and CD3 (T cells).

Late Complications of Treatment and Follow-Up

It is important to recognize that successful treatment may be associated with late complications that may not appear for decades. Among the major late-term complications are secondary malignancies, ischemic heart disease, anthracycline-related cardiotoxicity, and radiation- or bleomycin-induced pulmonary toxicity. The risk of developing myelodysplastic disorders and acute myeloid leukemia is related to alkylator and topoisomerase inhibitor use and is enhanced by radiation. Radiation therapy increases the risk of malignancy in the treatment region, particularly breast cancer in women and lung cancer in smokers.

Surveillance for DLBCL for patients in remission can vary but generally involves visits every 3 or 4 months for 2 years, and every 6 months or annually thereafter. During these visits, examination of the LN areas, abdomen, thyroid, and skin is important. CT scans are recommended in early follow-up, particularly for high-risk patients or those with uncertain posttreatment imaging findings, but do not commonly detect relapse in asymptomatic patients and have not been shown to improve survival. FDG-PET scans are not recommended for routine follow-up because the high rate of false-positive scans is unlikely to offset the value of early detection. Routine laboratory studies with blood counts, liver function tests, and LDH should be performed. Thyroid-stimulating hormone levels should be monitored annually in patients who received neck radiotherapy. Women who received thoracic irradiation may require enhanced breast cancer screening, depending on age of exposure, and may include annual mammography and breast MRI starting 10 years after radiation therapy. Mammography for females should begin 10 years from the diagnosis of lymphoma or at age 40 years, whichever comes first.

FUTURE DIRECTIONS

Over recent years, we have made significant advances in elucidating the molecular biology of DLBCL and BL, and this has led to an era of enhanced and exciting drug discovery. In DLBCL in particular, many critical pathways and novel mutations have been identified, and many new agents are being investigated. The promising activity of novel strategies such as anti-CD19 CAR-T cells, novel antibodies and bispecific antibodies in the relapsed/refractory setting has led to their investigation in the upfront setting which is currently underway, principally in high-risk groups of patients.

CHAPTER 86

MANTLE CELL LYMPHOMA

Julie M. Vose

Mantle cell lymphoma (MCL) is a distinct subtype of mature B-cell non-Hodgkin lymphoma (NHL) that accounts for 5% to 10% of all NHL. Although a subset of patients with MCL may have an indolent course, MCL is generally an aggressive NHL. In the 1970s, the Kiel classification used the terminology *centrocytic lymphoma* to describe MCL, whereas Berard and Dorfman categorized it as *lymphocytic lymphoma of intermediate differentiation*. In the 1980s, the term *mantle-zone lymphoma* was used to denote a distinct subtype of MCL, characterized by the proliferation of atypical, small lymphoid cells with wide mantles around benign germinal centers (GCs). In the Revised European–American Lymphoma classification in 1994, 2001, 2008, and 2016, the WHO classification of tumors of hematopoietic and lymphoid tissues recognized MCL as a distinct disease under mature B-cell lymphomas. In recent years, with the recognition as a distinct entity, significant progress has been made toward understanding the underlying pathogenesis of MCL and translating that knowledge to design more effective therapies.[1]

EPIDEMIOLOGY

MCL represents 6% to 10% of all lymphomas and is two- to sevenfold more common in men than women and almost twofold more common in people of European ancestry than African Americans. The average age at diagnosis varies between 60 and 70 years. The annual incidence is approximately four to eight cases per million population in the United States and Europe.[2]

PATHOBIOLOGY

MCL, characterized by an alteration in the regulation of the cell cycle, demonstrates cyclin D1 overexpression and increased replication. The tumor cells also demonstrate decreased response to DNA damage and resistance to apoptosis. The tumor cells originate from pre-B cells in the bone marrow that can follow at least two different molecular pathways of development.

The classic MCL originates from a naïve B cell that has not entered the follicular GC but has SOX11 expression, lambda light chain restriction, and limited or no immunoglobulin heavy chain variable (IgVH) somatic mutations. SOX11 expression is associated with the activation of histone marks and absence of DNA methylation. The second subset of MCL, an indolent form typically limited to peripheral blood, bone marrow, and spleen, originates from post-GC B cells. This MCL subset has frequent IgVH mutations, typically lacks SOX11 expression, and has kappa light chain restriction. A few studies have demonstrated a correlation between SOX11 expression and aggressive tumors with high serum levels of lactate dehydrogenase (LDH) and high Ki-67 index. Conversely, SOX11-negative MCL may occasionally acquire complex karyotype and TP53 alterations, transforming into an aggressive tumor (Fig. 86.1).[3]

Genetic Alteration of Proliferative Pathways

The three most common recurrent mutations in MCL involve *CCND1* (also known as cyclin D1, BCL1, or PRAD1), *TP53*, and ataxia-telangiectasia mutated (*ATM*) genes. The vast majority of MCL have the reciprocal translocation, t(11;14) (q13;q23), which juxtaposes *CCND1* gene to the immunoglobin heavy-chain locus. The consequent overexpression of *CCND1* gene, located at 11q13, encodes cyclin D1 protein. Cyclin D1 protein, which is not expressed in normal lymphocytes, is expressed in virtually all MCL and at a lower level in Burkitt lymphoma and acute lymphoblastic lymphoma (ALL). A few cells with t(11;14) have been found in the blood of 1% to 2% of healthy individuals. Therefore, cyclin D1 overexpression is not sufficient for the transformation of normal B cells to MCL, rather it is thought to represent an early genetic event. Interestingly, the close physical proximity of the chromosomal regions of the IgVH and CCND1 loci in the nucleus of immature lymphoid B cells may facilitate the occurrence of recurrent translocations. Furthermore, colocalization and interaction of IgVH-CCND1 chromosomal segment and a transcription factor called *nucleolin* near the perinucleolar area leads to the transcription of cyclin D1 protein. Cyclin D1 protein then regulates the G1 phase by binding to cyclin-dependent kinase (CDK) 4 and CDK6. The cyclin D1-CDK complex phosphorylates retinoblastoma 1 (RB1), resulting in a release of E2F transcription factor and transition of a cell from G1 to S phase. Additionally, the *CDKN2A* gene on chromosome 9p, which regulates INK4a protein, is deleted in 20% to 30% of highly proliferating MCL. The INK4a protein inhibits CDK4 and CDK6 and thus maintains the RB1 protein in its active, antiproliferative state. INK4a is frequently deleted in MCL and cooperates with *CCND1* gene. Therefore, the CDKN2A-INK4a-CDK4-RB1 pathway is dysregulated in patients with MCL, particularly those with blastoid histology.[3–5]

Recent studies have described cyclin D1-negative MCL cases that demonstrate pathologic features and gene expression profile, similar to cyclin D1–positive MCL. Cyclin D1–negative MCL is associated with the dysregulation in the expression of the following genes (often due to epigenetic changes): overexpression of cyclin D2 or D3; decreased CDK inhibitor 1B (CDKI1B or p27); upregulation of cyclin E; or inactivation of *RB* gene. CDKI1B protein regulates the cell progression from G1 to S phase by inhibiting the cyclin E/CDK2 complex (the latter also inactivates the RB protein). Although the diagnosis of cyclin D1–negative MCL is uncommon and requires caution, these cases highlight the relevance of the oncogenic dysregulation of the cell cycle, especially of the G1 phase in the pathogenesis of MCL.[4]

Antiapoptotic and Prosurvival Pathways

Some patients with aggressive MCL, particularly the blastoid variant, have an increased number of chromosomal abnormalities, such as complex karyotype and tetraploidy. The accumulation of chromosomal abnormalities suggests alterations in the DNA damage response pathways. *TP53* mutation and deletion or point mutation of the *ATM* gene (located at 11q22–q23) are recurrent mutations in MCL. *TP53* mutations, associated with alterations of 17p chromosomal segment, are present in 10% to 28% of MCL cases. These point mutations are frequently missense mutations that compromise normal p53 expression. The *TP53* tumor suppressor gene normally regulates the cell cycle, DNA repair, apoptosis, senescence, and autophagy through transcription-dependent and independent pathways. Disruption in TP53-dependent apoptosis has also been linked to deletion, mutation, or silencing of *BIM* and *NOXA* genes. The latter two genes transcribe proapoptotic proteins important in Bax/Bak-mediated

cytochrome C release, which is essential to apoptosis. TP53 expression is also inhibited by the binding of PAX5 transcription factor to the TP53 promoter. PAX5 is upregulated by SOX11 in a significant number of patients with MCL. PAX5 represses PRDM1/BLIMP1 and negatively regulates differentiation of early lymphoid progenitors to plasma cells. Therefore, the SOX11-PAX5-PRDM1/BLIMP1 axis suppresses B-cell differentiation to plasma cells and plays an important role in the pathogenesis of MCL. MDM2 is another protein overexpressed in about 16% of MCL and mediates polyubiquitination and degradation of p53. This function of MDM2 protein is prevented by ARF protein, also known as p14 (encoded by *CDKN2A* gene). In MCL, however, the homozygous deletion of the *CDKN2A* gene allows MDM2-mediated degradation of TP53 and dysregulation of apoptotic pathways.[3,5]

Inactivation of the *ATM* gene, detected in about 40% of MCL, facilitates genomic instability by impairing responses to DNA damage. Intriguingly, the inactivation of *ATM*, perhaps an early phenomenon in MCL, is not commonly seen in other lymphomas—except in T-cell prolymphocytic leukemia. *ATM* encodes the PI3K protein, which phosphorylates p53, promoting its stabilization and transcriptional activation, therefore leading to cell-cycle arrest, DNA repair, or apoptosis. Consequently, inactivation of *ATM* causes genomic instability by inactivation of p53. Despite having similar pathogenic significance, *ATM* mutations do not impact overall survival, whereas *TP53* mutations do predict for worse survival. In addition, *ATM* may play a role in activation of the nuclear factor kappaB (NFκB) by phosphorylation of the NFκB inhibitor, IkappaB. The NFκB-signaling regulates transcription factors that activate numerous genes involved in cell survival, apoptosis, and cell migration. Its persistent activity is associated with tumor formation, tumor growth, metastasis, and drug resistance, in B-cell lymphomas and other cancers. Notably, the PI3K-AKT pathway is upstream of the mammalian target of rapamycin (mTOR), which in turn is upstream of cyclin D1, CDKI1B, and other regulatory proteins. Conversely, CHK2 and CHK1 are kinases downstream of ATM and prevent cell-cycle progression in response to ATM. Downregulation or mutations of CHK2 and CHK1 are also commonly seen in MCL.

Wnt canonical and Sonic Hedgehog (SHH) pathways are also altered in MCL. The Wnt canonical pathway, via β-catenin and important for normal cell growth and development, is constitutively activated in a subset of MCL and may promote tumor growth. Similarly, SHH-GLI-signaling molecules such as PTCH and SMO receptors, as well as GLI1 and GLI2 transcription factors, are expressed in MCL and may contribute to the proliferation of MCL.

Lastly, dysregulation of the B-cell receptor (BCR), a key player of normal B-cell differentiation and development, is involved in the pathogenesis of MCL. Activation of BCR-associated kinases (spleen tyrosine kinase [SYK], Bruton tyrosine kinase [BTK], and protein kinase C-beta [PKC-β]) is observed in MCL. BTK, a member of the Tec family of nonreceptor protein tyrosine kinases, has a well-defined role in the constitutively activated BCR signaling pathway in MCL. Amplification and overexpression of SYK have been found in a subset of MCL. SYK, LYN, and BTK are frequently phosphorylated in MCL, suggesting activation of the BCR pathway. Therefore, the BCR pathway appears to contribute to the growth and survival of MCL cells. The signaling pathways that contribute to the pathogenesis are summarized in Fig. 86.2.

CLINICAL MANIFESTATIONS

The early symptoms sometimes include fever, night sweats, unexplained weight loss, lymphadenopathy, and splenomegaly. Typically, the majority of patients present at an advanced stage (III or IV) with lymphadenopathy, hepatomegaly, splenomegaly, and bone marrow

Figure 86.2 THE SIGNALING PATHWAYS CONTRIBUTING TO MANTLE CELL LYMPHOMA PATHOGENESIS. *CCND1* translocation and mutation of *TP53* and ataxia-telangiectasia mutated (*ATM*) genes are common genetic alterations involved in the pathogenesis of mantle cell lymphoma (MCL). Cyclin D1 protein regulates the G1 phase by binding to cyclin-dependent kinase (CDK) 4 and CDK6. The cyclin D1-CDK complex phosphorylates retinoblastoma 1 (RB1) resulting in release of E2F transcription factor and transition of a cell from G1 to S phase. Other major abnormalities include inactivation of the ATM, and cell cycle checkpoint kinase (CHK 1 and CHK2) genes; MDM2-mediated degradation of TP53; activation of B cell receptor-associated kinases and constitutive activation of nuclear factor kappaB (NFκB), PI3K/AKT/mammalian target of rapamycin (mTOR), Wnt canonical, and Sonic Hedgehog (SHH) pathways.

involvement. Splenomegaly is noted in 40% of patients and approximately 50% of patients present with circulating lymphoma cells. MCL also tends to involve extranodal sites, especially in the gastrointestinal (GI) tract. Involvement of the GI tract, frequently in the form of lymphomatous polyposis, can be detected in up to 90% of patients; however, many patients do not have any pertinent GI symptoms. During disease progression, MCL can infiltrate other organs including the respiratory tract, breast, or orbit. Involvement of the central nervous system (CNS) is rare but may be relatively more common with blastoid MCL and relapsed disease.

LABORATORY MANIFESTATIONS

Cytopenias are typically present secondary to bone marrow involvement and/or splenomegaly, whereas autoimmune cytopenias are rare. Elevation of LDH and uric acid correlates with tumor burden. Liver function tests may be abnormal if there is hepatic involvement. Other findings include elevated beta 2-microglobulin and, rarely, hypogammaglobulinemia or monoclonal gammopathy.

Histologically, the 2016 WHO classification[4] describes classic MCL as a monomorphic proliferation of small- to medium-sized lymphoid cells, with an irregular nuclear border, dispersed chromatin, and inconspicuous nucleoli. The architectural patterns may include a vaguely nodular and diffuse mantle zone or, rarely, follicular growth pattern. Infrequent cases, referred to as in situ MCL, may exclusively involve the inner mantle zones or narrow mantles. Histologic transformation to large B-cell lymphoma does not occur; however, MCL can have several morphologic variants, including aggressive blastoid and pleomorphic variants (Fig. 86.3).

1. Blastoid variant: lymphoma cells have a high mitotic rate (20 to 30 per 10 high-power fields) and dispersed chromatin; frequently resembles lymphoblasts.
2. Pleomorphic variant: cells have different forms including frequent large cells, pale cytoplasm, oval to irregular nuclear border, and often prominent nucleoli.

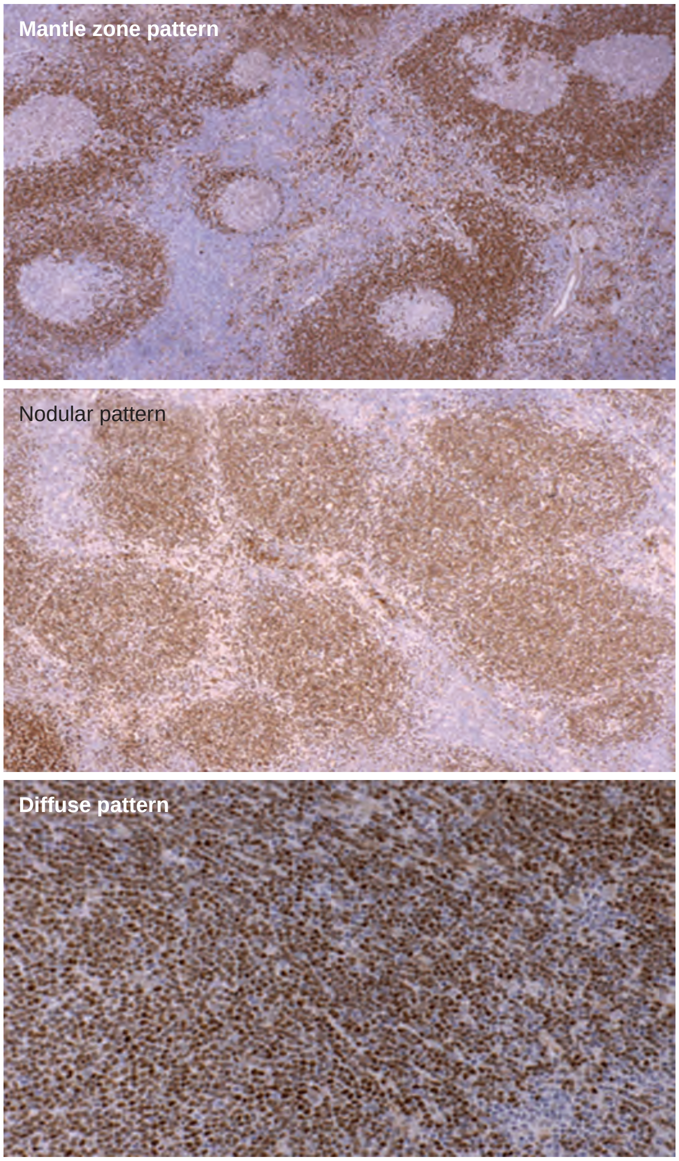

Figure 86.3 HISTOPATHOLOGIC SUBTYPES OF MANTLE CELL LYMPHOMA.

3. Small cell variant: cells are small and round with clumped chromatin; frequently resembles small lymphocytic lymphoma (SLL).
4. Marginal zone-like variant: this variant has clusters of marginal zone-like or monocytoid B cells, with abundant pale cytoplasm.

DIAGNOSIS

The diagnosis of MCL is based on the morphologic, immunophenotypic, and genetic features evaluated on biopsied tissue. The inclusion of immunophenotyping increased the diagnostic consensus between expert hematopathologists in the International NHL Classification project from 77% (based on histology) to 87%. The characteristic, immunophenotypic features of MCL include an expression of the B cell–associated antigens CD19, CD20, CD22, and CD79a, an aberrant expression of the T cell–associated antigens CD5 and CD43, and a lack of expression of CD3, CD10, and CD23. The identification of t(11;14)(q13;q32) and CCND1 oncogene can further aid to the diagnostic accuracy.[4,5] The presence of CCND1 oncogene is revealed most accurately in stains of formalin-fixed, paraffin-embedded lymph nodes or in soft tissue. Nonetheless, the cyclin D1 overexpression can also be seen in a subset of patients with ALL, Burkitt lymphoma, hairy cell leukemia, and multiple myeloma. The t(11;14) is seen in more than half of patients on karyotyping and in virtually all the patients screened with fluorescence in situ hybridization. In patients with cyclin D1–negative MCL, overexpression of cyclin D2, cyclin D3, or SOX11 can help in establishing the diagnosis. However, cyclin D2 is also overexpressed in patients with chronic lymphocytic leukemia and lymphoplasmacytic lymphoma, and cyclin D3 can be overexpressed in the vast majority of B-cell malignancies. Overexpression of SOX11, present in more than 90% of the patients with MCL, can also be seen in ALL, T-cell prolymphocytic leukemia, and Burkitt lymphoma. However, these other entities are usually easier to differentiate by clinicopathologic and other criteria; therefore, SOX11 is a very useful tool in cyclin D1–negative cases.

Differential Diagnosis

MCL should be differentiated from other B-cell NHL, particularly SLL/chronic lymphocytic leukemia, lymphoplasmacytic lymphoma, marginal-zone lymphoma, and follicular lymphoma. Additionally, with minimal differentiation, the blastoid variant MCL may resemble B-cell ALL and acute myeloid leukemia. Immunophenotypic markers are helpful in differentiating MCL (CD5$^+$, CD10$^-$, CD19$^+$, CD23$^-$, FMC$^+$) from SLL/chronic lymphocytic leukemia (CD5$^+$, CD10$^-$, CD19$^+$, CD23$^+$, FMC$^-$) and follicular lymphoma (CD5$^-$, CD10$^+$, CD19$^+$). In CD5-negative or cyclin D1–negative MCL, careful exclusion of other lymphomas, via detection of overexpression of cyclin D2, cyclin D3 or SOX11 and gene expression profiling, may help in the diagnosis.

Staging

Staging procedures include a complete blood count, comprehensive metabolic panel, LDH, evaluation of a bone marrow biopsy, and computed tomography (CT) of chest, abdomen, and pelvis. Although endoscopies of upper and lower GI tracts are frequently positive, such evaluation did not change management in a retrospective study. MCL has low to intermediate avidity for fluorodeoxyglucose (FDG); however, the blastoid variant is more FDG-avid. Nonetheless, an integrated FDG positron emission tomography (PET) and CT scan is frequently utilized for staging of patients with MCL. Lumbar puncture is not routinely performed but should be done in patients with neurologic symptoms or blastoid subtype. Hepatitis B serologies are performed prior to the use of rituximab because of a risk of reactivation.

THERAPY

MCL often combines the worst features of both follicular lymphoma (noncurability) and diffuse, large B-cell lymphoma (aggressive course). A paucity of randomized controlled trials, consequent to disease rarity, has resulted in a lack of standard therapy. Therapy options range from wait-and-watch strategy in select asymptomatic patients to intensified chemotherapy followed by upfront high-dose chemotherapy (HDT) and autologous hematopoietic stem cell transplant (ASCT) in young fit patients.[1]

Wait-and-Watch Strategy

The approach of watchful waiting, as utilized in other indolent lymphomas, has been advocated by some investigators in select patients with MCL. This recommendation is supported by a study from Weill Cornell Medical College among 97 patients with MCL. The study compared the outcomes between early treatment and observation groups. Among the observation group, the median time to treatment was 12 months (4 to 128 months). Patients in the observation group had better performance status (PS) and were more likely to have lower-risk standard International Prognostic Index scores than the early treatment group. The study demonstrated that a delay in initiation of therapy did not influence overall survival (OS) in a multivariate analysis.[6] Good outcomes with initial wait-and-watch approach were demonstrated in other studies from the United Kingdom and Sweden. Although these retrospective studies may have limitations, the wait-and-watch strategy is reasonable in asymptomatic older patients, who emphasize on delaying the use of noncurative therapy to preserve the quality of life.

Therapy Options: Non-Transplant Directed

When a decision has been made to start treatment, several chemo-immunotherapy regimens are available: alkylator-based (cyclophosphamide, vincristine, and prednisone [CVP]), anthracycline-based (cyclophosphamide, doxorubicin, vincristine and prednisone [CHOP]), fludarabine-based (fludarabine, cyclophosphamide, and mitoxantrone [FCM]), bendamustine-based (bendamustine and rituximab [BR]), cytarabine- and/or methotrexate-based (cyclophosphamide, vincristine, doxorubicin, and dexamethasone alternating with cytarabine and methotrexate [hyper-CVAD/MA]) regimens, cytarabine-based regimens without methotrexate (cisplatin, cytarabine, and dexamethasone [DHAP]), or alternating CHOP with DHAP; all are typically combined with rituximab in the current era.[7–16] More recently, attempts to incorporate agents used for relapsed MCL, such as bortezomib, ibrutinib, or lenalidomide in upfront therapy, have shown promising results.[17–20] With conventional chemotherapy such as rituximab and CHOP (R-CHOP), the median remission duration is 1.5 to 3 years.[7–9] Table 86.1 outlines front-line studies for combination therapies, without autologous stem-cell transplantation (ASCT).

Therapy Options: Upfront Intensified With or Without Consolidation Autologous Stem Cell Transplantation

Several studies have demonstrated improved outcomes with upfront intensified therapy, either alone or followed by high-dose chemotherapy and ASCT, in young symptomatic patients with MCL. In a randomized trial conducted in the pre-rituximab era by the European MCL network, the use of myeloablative radiochemotherapy and ASCT, versus α-interferon maintenance, following CHOP-like regimen, improved median PFS (39 vs. 17 months, $P = .01$) This occurred in 122 MCL patients without OS benefit (83% vs. 77% at 3 years, $P = 0.18$) and who were also ≤ 65 years old in the first complete remission.[21] In an MDACC study, 97 treatment-naïve MCL patients received rituximab-HyperCVAD and R-methotrexate/cytarabine alternating. The overall response rate was high with 87% of the patients having a complete response.[22] In the rituximab era, several nonrandomized prospective and retrospective studies have demonstrated better survival outcomes through intensified therapy

ASCT, Autologous stem cell transplantation; *CHOP*, cyclophosphamide, doxorubicin, vincristine and prednisone; *EFS*, event-free survival; *HDT*, high-dose chemotherapy; *PSCT*, peripheral stem cell transplant; *R-CHOP*, rituximab and CHOP.

and HDT/ASCT, compared with historical controls. The second Nordic MCL trial, among untreated patients with MCL <66 years ($n = 160$), utilized a phase II protocol with dose-intensified induction immunochemotherapy with maxi-CHOP-R (dose-intensified R-CHOP), alternating with rituximab and high-dose cytarabine, followed by HDT and rituximab-in vivo purged ASCT among the responders. This resulted in a 6-year OS and event-free survival (EFS) of 70% and 56%, respectively, with a higher proportion of molecular response rate (92% vs. 38%, $P < .001$), compared with a historical control in the first Nordic MCL trial.[23] Cancer and Leukemia Group B (CALGB) 59909 study demonstrated a 5-year PFS and OS of 56% and 64%, respectively, among patients with MCL who were up to the age of 69 years ($n = 78$) and who were treated with cytarabine- and methotrexate-based immunochemotherapy, followed by HDT/ASCT.[24] Several other studies have demonstrated excellent outcomes with rituximab-based chemotherapy, such as R-Hyper-CVAD, R-CHOP/RDHAP (rituximab, cisplatin, cytarabine and dexamethasone), or BR and HDT/ASCT (Table 86.2).[25–30] It is currently not clear if the choice of induction therapy makes a difference in the long-term outcomes of patients going on to receive HDT/ASCT, as long as the patient is in a good CR at the time of transplant.

Although these studies demonstrate improved progression-free survival (PFS) with HDT/ASCT consolidation, the optimal induction therapy is unclear. In order to determine the value of induction therapy, an NCCN NHL-database study compared the outcomes of patients with MCL <65 years, treated with several chemotherapy regimens. This study demonstrated a worse 3-year PFS with R-CHOP alone (18%), compared with R-Hyper-CVAD (58%, $P < .001$), R-CHOP and HDT/ASCT (56%, $P < .001$), and R-Hyper-CVAD and HDT/ASCT (55%, $P = .004$). PFS did not differ between the latter three groups. The 3-year OS was similar between R-CHOP alone (69%), R-Hyper-CVAD (85%, $P < .07$), and R-CHOP and HDT/ASCT (87%, $P < .20$). Multivariable analysis revealed that R-CHOP alone had worse OS compared with R-Hyper-CVAD but not worse compared to R-CHOP and HDT/ASCT.[31] Similarly, the type of induction therapy or the timing of therapy did not predict OS in 118 MCL patients who were treated with HDT/ASCT in another study. The use of R-Hyper-CVAD, compared with R-CHOP-like therapy, improved PFS for the entire MCL cohort ($P = .01$) but not among transplant recipients ($P = .26$). These studies indicate that intensive induction therapy, such as R-Hyper-CVAD, may be preferred to R-CHOP among patients who are not planned to undergo HDT/ASCT consolidation; however, the choice of initial therapy may not make a significant difference in OS of patients who are scheduled to undergo HDT/ASCT.[32]

In one study, the use of pre-emptive rituximab therapy (375 mg/m^2 weekly for 4 weeks) for molecular relapse, after upfront HDT/ASCT, resulted in re-induction of molecular remission in 92% and median molecular and clinical relapse-free survivals of 1.5 and 3.7 years, respectively.[33] Rituximab maintenance, after R-Hyper-CVAD or upfront HDT/ASCT, may also improve PFS.[34] The use of rituximab frequently increases the risk of neutropenia and hypogammaglobulinemia; however, this may not necessarily translate to a substantially increased risk of major infections.

Since we do not know the need for HDT/ASCT in MCL patients with negative minimal residual disease (MRD) after induction therapy, a United States intergroup study, EA4151, is randomizing patients who are MRD-negative after their induction to either rituximab maintenance × 3 years versus HDT/ASCT and then rituximab maintenance × 3 years (NCT3267433).

Central Nervous System Prophylaxis

The incidence of CNS involvement at diagnosis and the role of primary CNS prophylaxis in MCL are controversial. In relapsed MCL, CNS involvement is noted in up to 5% to 20% of patients, particularly those with blastoid variant and those that portend a poor prognosis. CNS-penetrating agents such as high-dose methotrexate and cytarabine, with or without intrathecal chemotherapy, may provide sufficient CNS prophylaxis in patients undergoing intensive therapies. In other patients with high-risk features such as blastoid morphology or presence of neurologic symptoms, some centers perform lumbar puncture and utilize intrathecal methotrexate or high-dose systemic methotrexate. Ibrutinib and lenalidomide have both been found to cross the blood-brain barrier and may be useful in some cases of CNS disease.

Relapsed or Refractory Mantle-Cell Lymphoma

Despite induction therapy, most patients with MCL will relapse and require subsequent therapies. The choice of therapy in relapsed or refractory MCL depends on the upfront chemotherapy regimen, outcomes with initial therapy, PS, comorbidities, and desired goals. Several options are FDA approved and available bortezomib,

TABLE 86.3 **Outcomes of Therapy Utilized in Relapsed/Refractory Mantle Cell Lymphoma**

Author, Year	Number of Patients	Therapy	ORR (%)	EFS/PFS (%)	OS (%)
[35]Goy, 2009	141	Bortezomib	32%	5 months	22 months
[36]Rummel, 2005	63	Bendamustine + rituximab	75%	Median 18 months	55% at 4 years
[37]Wang, 2012	44	Lenalidomide + rituximab	57%	11 months	24 months
[38]Rule, 2019	370	Ibrutinib	69.7%	12.5 months median	26.7 months median
[39]Wang, 2018	124	Acalabrutinib	81%	67% at 12 months	87% at 12 months
[40]Song, 2018	86	Zanubrutinib	84%	82% at 6 months	N/A
[43]Eyre, 2019	20	Venetoclax	53%	3 months	9.4 months
[44]Wang, 2020	74	KTE-X19 CAR-T cell	93%	61% at 12 months	83% at 12 months

CAR, Chimeric antigen receptor; *EFS*, event-free survival.

bendamustine, or lenalidomide, which are often combined with rituximab.[35–37] BTK inhibitors, such as ibrutinib, acalabrutinib, or zanubrutinib, have more recently been approved and used extensively for relapsed MCL.[38–40] Ibrutinib received an accelerated approval in November of 2013 based on a phase II study of relapsed or refractory MCL ($n = 111$), which demonstrated an overall response rate of 68%, with an OS of 58% at 18 months.[38] Acalabrutinib is an oral irreversible BTKi, with less off-target inhibition of similar kinases in comparison to ibrutinib.[41] The safety profile of acalabrutinib and a more recent approval of zanubrutinib may have less atrial fibrillation and bleeding risks than ibrutinib, but only a head-to-head comparison will show this definitively.[42] Other agents that are FDA approved for relapsed MCL include venetoclax or brexucabtagene autoleucel (Table 86.3).[43,44]

A new class of BTKi targets BTK via noncovalent, reversible inhibition. Unlike the irreversible BTKi, this class does not bind BTK at the C481 residue and thus would be expected to be unaffected by BTK binding site mutations. Mutations within the BTK binding site (most commonly C481S) are a well-characterized resistance mechanism to second-generation BTKi.[45] Preliminary results from phase I/II trials, with several agents in this class, show activity in B-cell malignancies, including BTKi relapsed MCL.[46,47]

Cellular Therapy in Relapsed/Refractory Mantle Cell Lymphoma

Patients who have not undergone upfront HDT/ASCT may benefit from HDT/ASCT, after salvage therapy. In one study, the use of HDT/ASCT demonstrated a median EFS and OS of 36% and 65%, respectively.[48]

With the advent of CD19-directed chimeric antigen receptor (CAR) T-cell therapy for the treatment of other B-cell malignancies, the ZUMA-2 trial tested brexucabtagene autoleucel (KTE-X19, an autologous CD19 CAR-T-cell construct).[44] Of the 74 patients enrolled on the trial, 68 had the product infused. Of the eligible patients, the overall response rate (ORR) was 93% and the complete response (CR) rate was 68%. Cytokine release syndrome and neurotoxicity, at a grade three or higher, was 15% and 31%, respectively. Infectious adverse events occurred twice at grade level five.[44] This therapy is now FDA approved and also undergoing further combination or sequential studies.

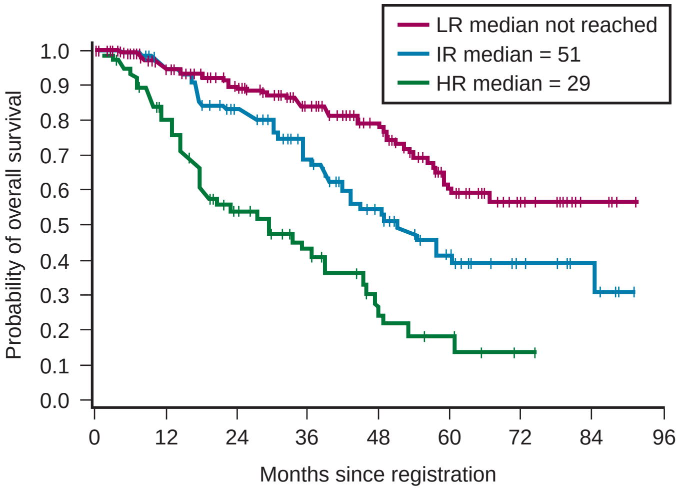
Although allogeneic stem cell transplantation (alloSCT) is potentially curative, lack of large-scale randomized trials and high transplant-related mortality (TRM) has limited enthusiasm toward the use of alloSCT to treat MCL. Nonetheless, alloSCT should be considered in young and fit MCL patients with multiple relapsed disease or ASCT failure. The outcomes of alloSCT have been compared with those of ASCT in a few studies. In a Center for International Blood and Marrow Transplant Research (CIBMTR), retrospective study of chemosensitive patients with MCL ($n = 519$) and reduced intensity conditioning (RIC) alloSCT resulted in lower relapse/progression, compared with ASCT. This was offset by a higher non-relapse mortality (NRM); hence, the 5-year OS was similar between the two groups. ASCT in first complete remission was associated with the highest OS and PFS, confirming the results of prior studies of upfront HDT/ASCT.[49] In these studies, the comparable OS with alloSCT, compared with ASCT, also demonstrates the efficacy of disease control with alloSCT in patients with multiple relapses. In clinical practice, therefore, alloSCT may be utilized in heavily pretreated patients.

RIC has been explored with a hope to reduce TRM and expand alloSCT to older patients or patients with other comorbidities. In a study, 70 patients with relapsed and refractory MCL, including prior ASCT failures (34%), underwent RIC alloSCT, mainly with alemtuzumab-containing regimens. NRM, cumulative risk of relapse, PFS, and OS were 21%, 65%, 14%, and 37%, respectively, at 5 years. Among patients who relapsed, donor lymphocyte infusion (DLI) or a second RIC alloSCT resulted in a complete remission rate of 73%.[50] Hence, RIC and nonmyeloablative alloSCT, along with DLI for relapse, may be reasonable options in patients who are not candidates for myeloablative alloSCT.

PROGNOSIS

As discussed previously, complete remission is seen in up to two-thirds of patients with MCL, particularly with upfront intensive therapy; however, almost all patients will relapse and develop resistance to chemotherapy over time. Although the prognosis for newly diagnosed patients has improved over the last decades, the OS compares unfavorably with the more frequent NHLs, such as follicular lymphoma and diffuse, large B-cell lymphoma. A small subset of patients may follow a more indolent clinical course in the beginning, and these patients may have a clinical history that resembles a chronic lymphocytic leukemia.

Prior studies have identified several adverse prognostic factors, which include eastern cooperative oncology group (ECOG) PS ≥ 2, age >65 years, elevated LDH, elevated serum beta$_2$-microglobulin, hemoglobin level <12 g/dL, advanced stage, involvement of peripheral blood or extranodal sites ≥ 2, high cell proliferation rate (Ki-67, mitotic index or proliferation signature), blastoid variant histology, deletion or mutation of TP53, and secondary chromosomal aberrations (the presence of gain 3q, 12q, and 13q and losses of 6q, 9p, 11q, and 17p).[51] More recent studies have demonstrated that the MCL international prognostic index (MIPI), based on age, ECOG PS, LDH, and white-blood cell count, is one of the most important prognostic factors in MCL. In a large study, MIPI categorized MCL patients into low risk (0 to 3 scores; OS not reached at a median follow-up of 32 months), intermediate risk (4 to 5 scores; median OS of 51 months), and high risk (6 to 11 scores; median OS of 29 months) categories, with a significant difference in OS (Fig. 86.4).



Numbers of patients at risk

LR	180	153	131	99	69	39	15	4
IR	145	116	83	57	37	19	9	5
HR	84	58	29	19	8	5	1	0

Figure 86.4 PROGNOSTIC GROUPS STRATIFIED ACCORDING TO THE MANTLE CELL INTERNATIONAL PROGNOSTIC INDEX. *HR*, High risk; *IR*, intermediate risk; *LR*, low risk.

MIPI separated the survival curves better than IPI utilized for diffuse large B-cell lymphoma or follicular lymphoma (FLIPI).[52] Cell proliferation (Ki-67), but not number of mitoses per square millimeter, was an independent prognostic score.[53] Ki-67 and MIPI have been shown to independently predict PFS and OS in other studies also. Prognosis may also be influenced by disease status at ASCT or alloSCT, achievement of molecular remission after therapy.[54] In the modern era, molecular diagnostics such as gene expression profiling, genome-wide miRNA profiling, as well as a limited-gene model (based on five genes *RAN*, *MYC*, *TNFRSF10B*, *POLE2*, and *SLC29A2*), may also provide meaningful prognostic information; however, the lack of commercial testing and standardization, as well as high cost, limit their use in clinical practice.

FUTURE DIRECTIONS

Since the recognition of MCL as a separate entity, significant advancement has been made in the understanding of tumor biology, diagnostic, prognostic, and treatment approaches. At a population level, this has resulted in a significant improvement in OS of patients with MCL, with approximately half of the patients in the United States surviving beyond 5 years, in recent years. A few studies have demonstrated poor prognosis of blastoid-variant MCL. Intensified therapy, including upfront ASCT, may overcome this poor prognosis, which needs further exploration in prospective studies. The roles of radiotherapy and CNS prophylaxis are currently not well established and should be investigated. Integration of clinical parameters and gene expression profiling has a potential to improve prognostication. Such prognostication may identify an indolent subgroup that can be observed, as well as an aggressive subgroup that may be better served, with upfront intensive therapy. A development of prognosis-directed therapy is an ideal goal. Molecular markers such as clonal immunoglobulin heavy chain gene rearrangements and *SOX11* gene expression may be used to identify MRD. Although the correlation is not consistent, molecular remission has been correlated with long-term remission and PFS. Molecular relapse may precede clinical relapse and has been utilized to guide preemptive therapy, as discussed above. If confirmed in other prospective trials, MRD-based therapies may be utilized to improve PFS in the future. Elderly patients and patients with comorbidities generally have poor outcomes and should be enrolled in clinical trials of novel, well-tolerated agents or combinations. Improved prognostic tools, incorporation of MRD-based preemptive therapy, translation of molecular tumor biology to bedside in the form of novel targeted therapies, and integration of such therapies to upfront traditional chemoimmunotherapy regimens offer a potential to change the therapeutic landscape of MCL.

CHAPTER 87

VIRUS-ASSOCIATED LYMPHOMA

Katherine C. Rappazzo, Jennifer A. Kanakry, and Richard F. Ambinder

There are five well-characterized human viruses that are generally accepted as important in lymphomagenesis (Table 87.1). These viruses may infect tumor cells (or their progenitors) or may act at a distance. The genomes of Epstein-Barr virus (EBV), Kaposi sarcoma–associated herpesvirus (KSHV, also known as human herpesvirus 8 [HHV-8]), and human T-lymphotropic virus-1 (HTLV-1) are present in tumor cells. The viral genes expressed in tumor cells modulate cellular metabolism, proliferation, and cell death. By contrast, the human immunodeficiency virus (HIV) genome is generally not detected in tumor cells. Whether hepatitis C virus (HCV) genomes are present in lymphoma cells remains a subject of controversy.

Although viral infection plays a role in the pathogenesis of some lymphomas, lymphomagenesis is unusual. Only a small subset of infected people develops lymphoma, and most lymphomas arise years or decades after primary infection. Geography and associated environmental exposures, host genetic factors, and immune status all modify risk.

Aspects of the biology and epidemiology of each of these viruses and their relationship with lymphomagenesis are reviewed in this chapter. In addition, clinically important and distinctive features of diagnosis and treatment of the associated lymphomas are presented.

EPSTEIN-BARR VIRUS

Viral Biology

EBV is a gammaherpesvirus transmitted mainly through saliva.[1,2] Infected B cells are driven to proliferate until an immune response controls infection. Thereafter, the viral genome persists for life in memory B lymphocytes. These cells elude immune surveillance in part because of very restricted viral gene expression and antigen presentation. Occasionally there is activation of viral lytic gene expression, but T cell–mediated immune function keeps such proliferation in check.

In vitro, EBV immortalizes B cells such that they grow indefinitely as lymphoblastoid cell lines (LCLs) (Fig. 87.1). LCLs are tumorigenic in immunodeficient mice. In LCLs, viral genomes are present as circular, double-stranded deoxyribonucleic acid (DNA) episomes within the nucleus. The viral proteins required for immortalization include Epstein-Barr virus nuclear antigen-1 (EBNA1), a sequence-specific DNA-binding protein important in the maintenance of the viral episome; EBNA2, a transcription factor that has many effects similar to those of activated Notch receptors; and latent membrane protein-1 (LMP1), a constitutively activated member of the tumor necrosis factor receptor superfamily, which most closely resembles CD40.[3] LMP1 activates the nuclear factor-κB (NFκB) pathway, which modulates cell proliferation and apoptosis.[4] Several other EBV proteins are also required for immortalization. Although EBV immortalization of B cells in vitro may offer some insights into tumorigenesis, some caution is required in using LCL as a tumor model. Most EBV tumors, including tumors of B-lineage cells, do not express many of the viral genes required for lymphocyte immortalization. The only tumors that express the full complement of viral proteins required for immortalization are those that arise in the most profoundly immunocompromised patients. It has been suggested that there is an inverse relationship between cellular mutations and viral gene expression in tumors.[5]

EBV gene expression may directly drive proliferation or inhibit apoptotic pathways, as illustrated by lymphocyte immortalization. However, viral gene expression may also perturb normal lymphocyte biology. Thus LMP1 expression upregulates activation induced (cytidine) deaminase expression, which facilitates somatic hypermutation and immunoglobulin class switching.[6] LMP1 expression may also be important in the conversion of naive B cells to postgerminal center memory B cells. LMP2A allows B cells that lack normal immunoglobulin expression to escape regulatory checkpoints and survive.[7]

Epidemiology of Viral Infection

EBV infection is ubiquitous. The vast majority of adults are infected worldwide. Primary infection most often occurs in childhood and is asymptomatic, but it may present as infectious mononucleosis in older children and adults.[8] Other possible determinants of symptomatic primary infection include genetic factors and possibly the size of the viral inoculum.

Strain differences in EBV are well recognized.[9] There is general agreement that the type 1 strain EBV is most common worldwide and in tumors. However, the importance of these strain differences with regard to lymphomagenesis remains poorly understood. In addition, variations in the regulatory regions or coding regions of a variety of other genes, including *EBNA1, LMP1*, and *ZTA*, have been recognized and suggested to play a role in lymphomagenesis. A simple classification of latent viral gene expression recognizes three patterns, as shown in Table 87.2.

Epstein-Barr Virus Detection in Clinical Specimens

Detection of virus in tumor cells requires demonstration of viral DNA, RNA, or protein in tumor cells.[10] Although polymerase chain reaction (PCR) makes detection of viral DNA straightforward, the ubiquity of EBV infection and its persistence in a tiny fraction of B cells that harbor EBV means that EBV DNA is readily detected in many specimens that include normal lymphocytes. In pathology laboratories, immunohistochemistry for LMP1 is commonly employed and is sensitive for the detection of EBV in Hodgkin lymphoma (HL).[11] In a variety of other EBV-associated B- and T-cell malignancies, expression of LMP1 is more variable. Thus failure to detect LMP1 expression does not exclude the presence of EBV, except perhaps in HL. In situ hybridization to detect viral RNA in tissue specimens has emerged as the pathology laboratory standard. The viral RNAs targeted are the EBV-encoded RNA (EBER) RNAs that encode short non-coding RNA transcripts expressed at high copy number per cell. Whereas viral DNA is typically present at less than 100 copies/cell in tumor tissue, EBER RNAs are present in very high numbers (millions of copies).

TABLE 87.1 **Viruses and Lymphomagenesis**

Virus	Viral Genome in Tumor Cell	Lymphoma Type
EBV	Episomal	B, T, NK
KSHV	Episomal	B
HTLV-1	Integrated	T
HIV-1	Absent	B
HCV	Uncertain	B

EBV, Epstein-Barr virus; *HCV*, hepatitis C virus; *HIV-1*, human immunodeficiency virus type 1; *HTLV-1*, human T-lymphotropic virus-1; *KSHV*, Kaposi sarcoma–associated herpesvirus; *NK*, natural killer.

TABLE 87.2 **Patterns of Epstein-Barr Virus Gene Expression in Latency**

Latency	EBNA1	EBNA2, EBNA3A, EBNA3B, EBNA3C	LMP1	LMP2A
I	+			
II	+		+	+
III	+	+	+	+

EBNA, Epstein-Barr virus nuclear antigen; *EBV*, Epstein-Barr virus; *LMP*, latent membrane protein.

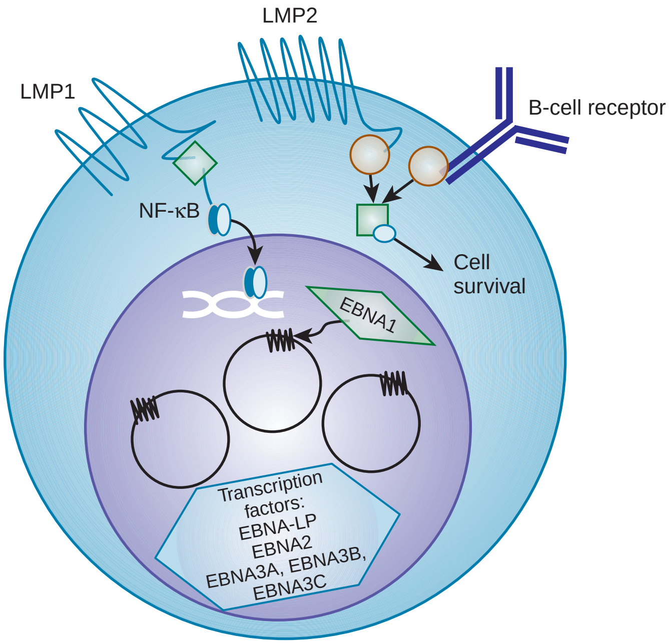

Figure 87.1 EPSTEIN-BARR VIRUS–IMMORTALIZED B CELL. Normal B cells are readily immortalized in vitro with EBV. These cells express EBV nuclear and membrane proteins. The nuclear proteins include a protein expressed in all EBV-associated tumors, Epstein-Barr virus nuclear antigen 1 (EBNA1). This protein is required for episomal maintenance. Other viral nuclear proteins expressed are transcription factors. These include EBNA-LP, EBNA2, EBNA3A, EBNA3B, and EBNA3C. Two membrane proteins are expressed: latent membrane protein 1 (LMP1), which activates nuclear factor-κB (NFκB) pathways, and LMP2A, which mimics B-cell receptor (immunoglobulin) signaling.

EBV-positive cancers typically have detectable viral DNA in the blood, making cell-free or plasma EBV DNA an attractive tumor marker.[12–14] Detection of EBV DNA in whole blood may reflect the presence of viral DNA in cells or in plasma. In cells the viral DNA may be present as linear double-stranded DNA molecules replicated by the viral DNA polymerase (to be packaged into virions) or as latent circular double stranded DNA plasmids associated with nuclear cell DNA and replicated by cellular enzymes with cell cycle. Virion DNA and viral DNA from latently infected cells that has been released following cell death is also measured in plasma. When blood has been fractionated and EBV DNA in peripheral blood mononuclear cells (PBMC) compared with EBV DNA in plasma, the correlation with EBV-associated disease is stronger with plasma.[15] It should be noted that many patients had detectable EBV DNA in PBMC and plasma without any EBV-associated disease (i.e., no EBV tumor nor evidence of infectious mononucleosis or other virus-related syndrome). Virion DNA is never methylated and recent reports have suggested that the presence of viral DNA in the absence of CpG methylation may make it less likely that a malignancy is the source of the viral DNA.[16,17] Further refinement of diagnostic tools that characterize EBV DNA methylation may be useful for improving the specificity of plasma EBV DNA for EBV-associated malignancies.

Association with Particular Types of Lymphoma

Some lymphoma types are nearly 100% EBV associated, including endemic Burkitt lymphoma (BL), extranodal natural killer (NK)/T-cell lymphoma of the nasal type, early posttransplantation lymphoproliferative disorder (PTLD), lymphomatoid granulomatosis, diffuse large B-cell lymphoma (DLBCL) associated with chronic inflammation, EBV-positive DLBCL of older adults, and AIDS primary central nervous system (CNS) lymphoma (PCNSL).[18–20] Other lymphoma types are variably EBV associated. These include classic HL, PTLDs occurring many months or years after transplantation, and systemic AIDS-related lymphoma.

Some lymphoma types appear never or almost never to be EBV associated, including most indolent B-cell lymphomas, although there is growing evidence that exceptions do exist, particularly in the setting of immunocompromise.[21–23] Thus, the spectrum of EBV-associated lymphomas continues to expand, and the presence of EBV might be an indication to consider an underlying immune defect in the patient.

Other lymphomas are typically not EBV associated but have the interesting feature of being associated with EBV upon transformation or upon development of de novo secondary lymphomas. For example, chronic lymphocytic leukemia (CLL) can transform into EBV-positive HL, and patients with angioimmunoblastic T-cell lymphoma (AITL) can rarely develop EBV-positive DLBCL.[24,25]

Table 87.3 lists the lymphomas that have been associated with EBV, associated cofactors, viral antigen expression, and an estimate of the percentage of tumors within each lymphoma subtype that harbor viral genomes. The table serves to illustrate the range of EBV lymphomas as well as host features that increase risk, but it is not meant to be comprehensive.

Posttransplantation Lymphoproliferative Disorder

PTLD is a group of lymphoproliferative disorders ranging from polyclonal lymphoid hyperplasia to lymphomas that arise in patients after solid organ or hematopoietic stem cell transplant (HSCT).[26] PTLD, especially in the first few months after transplant, is highly associated with EBV (Fig. 87.2A and B). EBV gene expression in PTLD most commonly corresponds to latencies II and III.[27] Broad expression of viral proteins is seen only in immunosuppressed hosts, reflecting that many of these proteins are immunogenic and commonly targeted by cytotoxic T cells.

B cells that harbor EBV are able to proliferate in the setting of posttransplant immunosuppression, at least in part because of decreased T-cell surveillance.[28] HSCT patients who receive grafts that have been

TABLE 87.3 Epstein-Barr Virus–Associated Lymphoma

Type	Cofactors	Viral Gene Expression	Approximate Percentage EBV Associated	Comment
PTLD	Immunosuppression, allograft	Latency II or III	50%–95%	Early days/months after transplantation are more commonly associated with EBV
Sporadic BL		Latency I	20% in the United States	Higher in Latin America
Endemic BL	Malaria	Latency I	>95%	
AIDS BL	HIV	Latency I	30%	
HL		Latency II	30% in the United States	Higher percentage in mixed cellularity, in males, in Hispanics
AIDS PCNSL	HIV	Latency II or III	>95%	
Extranodal NK/T-cell lymphoma, nasal type	More common in Asia	Latency II	>95%	
AIDS PEL	HIV and KSHV	Latency I	>75%	Rare cases of PEL in HIV-negative patients are typically EBV-negative
Lymphomatoid granulomatosis	Immunocompromise	Latency II	>90%	
Methotrexate-associated lymphoma	Methotrexate treatment	Latency III	>95%	May regress with withdrawal of methotrexate

AIDS, Acquired immunodeficiency syndrome; *BL*, Burkitt lymphoma; *EBV*, Epstein-Barr virus; *HIV*, human immunodeficiency virus; *HL*, Hodgkin lymphoma; *KSHV*, Kaposi sarcoma–associated herpesvirus; *NK*, natural killer; *PCNSL*, primary central nervous system lymphoma; *PEL*, primary effusion lymphoma; *PTLD*, posttransplantation lymphoproliferative disorder.

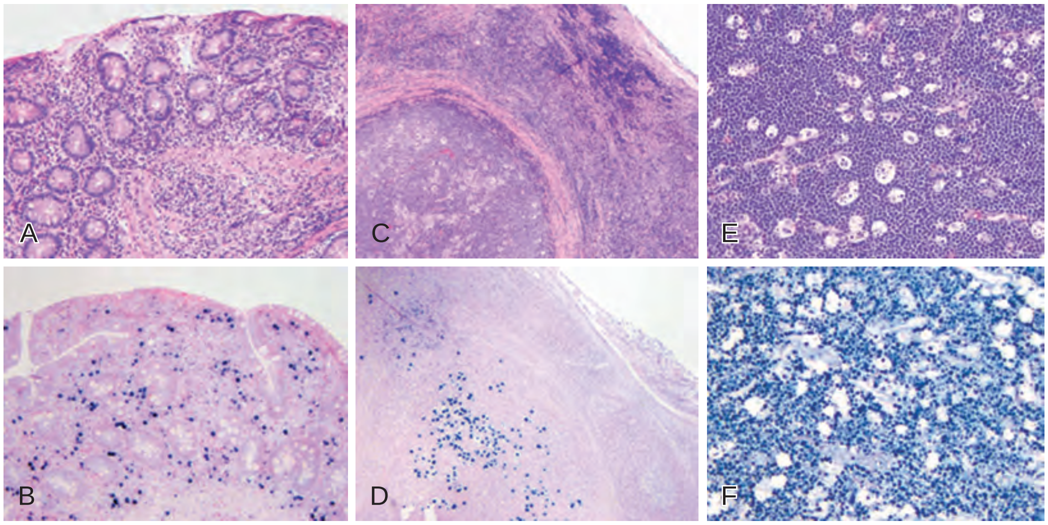

Figure 87.2 EXAMPLES OF EPSTEIN-BARR VIRUS–RELATED LYMPHOMAS. Posttransplant lymphoproliferative disorder (PTLD), polymorphic type, EBV-positive occurring in the gastrointestinal tract of a 15-month-old girl following an orthotopic liver transplant (A and B). There was a mildly atypical lymphocytic infiltrate in the duodenal mucosa composed of small lymphocytes, plasma cells, and occasional large cells (A). The infiltrate was EBV-positive, as demonstrated by in situ hybridization for Epstein-Barr–encoded RNA (EBER) (B). Hodgkin lymphoma, nodular sclerosing type, EBV-positive (C and D). The hematoxylin and eosin–stained section shows a portion of a lymph node from a cervical lymph node biopsy of an 8-year-old girl. There are bands of sclerosis forming a cellular nodule, and within the nodule there are a mixed inflammatory infiltrate and scattered large cells with contracted cytoplasm consistent with lacunar cells (C). The immunophenotype of these cells was that of classic Hodgkin lymphoma, and the cells were EBER-positive (D). EBV is seen more frequently in mixed-cellularity Hodgkin lymphoma but can be seen in 10% to 40% of cases of nodular sclerosing type. It is even more frequent in cases associated with human immunodeficiency virus (HIV; see text) and in resource-poor regions. Burkitt lymphoma, sporadic type, EBV-positive (E and F). A section of the cervical lymph node biopsy of a 9-year-old girl with a rapidly enlarging neck mass is shown. The section illustrates the classic morphologic features of Burkitt lymphoma with a “starry sky” appearance, sheets of intermediate-sized cells with multiple small nucleoli and high mitotic rate. The cells were virtually all EBER-positive (F). EBV can be seen in about 20% to 30% of cases of sporadic Burkitt lymphoma and is essentially always positive in endemic cases.

T-cell depleted develop EBV-associated PTLD at very high rates. Treatment of rejection in solid organ transplant recipients with agents such as the monoclonal antibody OKT3, which targets CD3$^+$ cells, is associated with markedly increased risk for PTLD.[29] Treatment strategies such as reduction of immunosuppression, use of rituximab, and infusion of EBV-specific cytotoxic T lymphocytes (CTL) have been effective in treating or preventing PTLD. A recent publication describing “off-the-shelf” third-party adoptive cell therapy for EBV-PTLD found overall response rates of 68% (for HSCT patients) and 54% (for solid organ transplantation), which is comparable to

EPSTEIN-BARR VIRUS–ASSOCIATED POSITIVE POSTTRANSPLANT LYMPHOPROLIFERATIVE DISORDER

A 55-year-old renal transplant patient presents with acute renal failure 5 months after transplant. She is found on imaging to have an obstructing mass in the transplanted kidney. She undergoes kidney biopsy, and EBV-PTLD involving the transplanted organ is diagnosed. Treatment options include decreasing immunosuppression (acknowledging the associated risk for organ rejection); changing immunosuppressive agents—switching a calcineurin inhibitor for a mammalian target of rapamycin (mTOR) inhibitor; rituximab followed by combination chemotherapy if remission is not achieved; adoptive T-cell therapy with autologous or third party EBV-specific T cells; or investigational therapies.

rates reported for donor-derived EBV-CTL (see box on Epstein-Barr Virus–Associated Positive Posttransplant Lymphoproliferative Disorder).[30]

Hodgkin Lymphoma

Approximately 30% of classic HL tumors in the United States and Europe are EBV-associated (see Fig. 87.2C and D).[31,32] Epidemiologic studies suggest that individuals with a history of symptomatic infectious mononucleosis are at increased risk for EBV-associated HL, but not for EBV-negative HL or other lymphomas.[33] The period of risk peaks at about 2 years but continues to be elevated for at least 10 years after symptomatic mononucleosis. In addition, specific HLA genes have been associated with an increased risk for EBV-associated HL.[34]

Higher EBV associations are seen in Latin America, Africa, and parts of Asia. Factors associated with EBV tumor positivity include mixed cellularity and lymphocyte-depleted classic HL histologic subtypes, male sex, low socioeconomic background, history of symptomatic infectious mononucleosis, and Hispanic ethnicity. Organ and hematopoietic stem cell transplant recipients, patients with primary immunodeficiencies, and HIV-positive patients are more likely to develop HL than the general population, and approximately 90% of the tumors in these settings are EBV-associated.[35]

The EBV gene expression pattern in HL is latency II, even when HL occurs in immunocompromised populations.[36] LMP1 and LMP2A may mimic signaling of B-cell receptors and thus protect B cells lacking functional immunoglobulin expression from apoptotic signaling. Approximately 20% of HLs lack productive immunoglobulin gene rearrangements. These tumors appear to be exclusively EBV-associated.

Patients with EBV-positive HL quite reliably have EBV DNA detected in cell-free blood (plasma or serum) in the setting of active disease.[13,37] Failure to clear EBV DNA from plasma or serum with therapy has been associated with inferior failure-free survival.

Currently, treatment regimens for EBV-positive HL do not differ from those used for EBV-negative HL. However, novel treatment strategies involving adoptive therapy with autologous EBV-specific T cells targeting type II latency LMP antigens appear to be associated with durable complete responses and low toxicity in some patients with EBV-positive HL, even in the setting of relapsed/refractory disease.[38,39]

Burkitt Lymphoma

Endemic BL is nearly 100% associated with EBV, whereas sporadic and HIV-associated BL are much more variably EBV-associated (see Table 87.3 and Fig. 87.2E and F).[40] Viral expression is latency I (i.e., EBNA1 is the only viral protein consistently expressed). The defining feature of BL is a translocation between c-Myc on chromosome 8 and one of the immunoglobulin genes on chromosome 2, 14, or 22. It has been generally presumed that *falciparum* malaria is a cofactor in endemic BL, and the distribution of BL in Africa corresponds to the distribution of holoendemic malaria. However, little is understood of the pathogenesis or interaction between these infectious cofactors.[41] The characteristic presentation of BL is different in the endemic versus sporadic settings, but there is no evidence to link these presentations specifically with the virus. Data has been presented suggesting that EBV DNA measurements in plasma may have utility in facilitating diagnosis, assessing prognosis, and monitoring tumor response in East Africa.[42] The virus-tumor association does not currently guide therapy.

KAPOSI SARCOMA–ASSOCIATED HERPESVIRUS

Virus and Tumor Epidemiology

KSHV (HHV-8) is a gammaherpesvirus that, unlike EBV, has a low prevalence worldwide.[43] The virus is endemic in certain areas, such as in sub-Saharan Africa and the Middle East, and has an intermediate prevalence in Mediterranean countries. Transmission is believed to be predominately through saliva. Similar to EBV, KSHV latently infects B cells, and viral genes that promote cell survival are implicated in lymphomagenesis.[44]

KSHV was discovered in Kaposi sarcoma but is also present in rare lymphoproliferative diseases, including primary effusion lymphoma

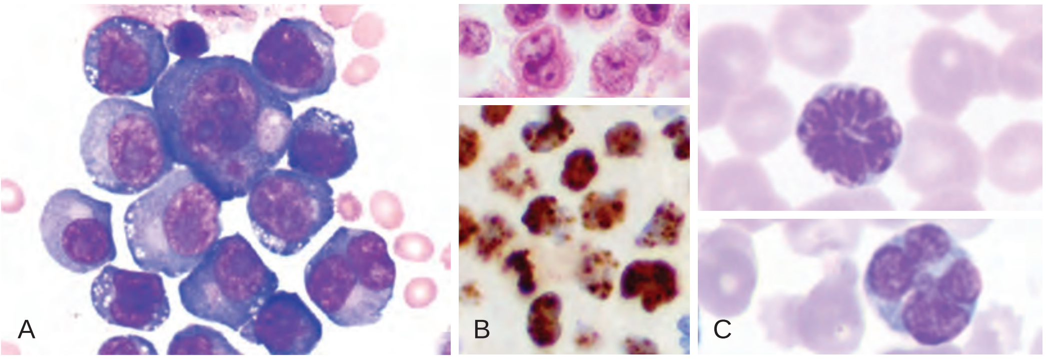

Figure 87.3 EXAMPLES OF KAPOSI SARCOMA–ASSOCIATED HERPESVIRUS AND HUMAN T-LYMPHOTROPIC VIRUS-1 (HTLV-1)–ASSOCIATED LYMPHOPROLIFERATIVE DISEASE. Primary effusion lymphoma (A and B). (A) The pleural tap had a high cell count, and the cytospin preparation revealed a markedly pleomorphic cell population with large and giant cells with deep-blue cytoplasm. (B) A cell block was prepared *(top)* so that in situ hybridization studies could be performed. These studies showed the cells to be KSHV positive by immunohistochemistry for latency associated nuclear antigen-1 (LANA-1) *(bottom)* and EBV positive by EBER in situ hybridization (not shown). (C) Adult T-cell leukemia/lymphoma in a patient who was HTLV-1 positive. The peripheral smear showed the classic "flower" cells. *EBER*, Epstein-Barr–encoded RNA. *(A and B, Courtesy Dr. Elizabeth Hyjek, University of Chicago.)*

(PEL) (Fig. 87.3A and B) and multicentric Castleman disease (MCD).[45] Other KSHV-positive lymphomas have been characterized, all of which tend to occur in severely immunocompromised individuals and carry a poor prognosis. PEL occurs almost exclusively in HIV-positive patients, typically when CD4 counts are less than 100/mm^3. However, PEL has been reported very rarely in solid organ transplant patients and elderly men with some degree of immunocompromise.[46] KSHV is always present in PEL. In HIV patients with PEL, tumor cells are usually dually infected with EBV as well. By contrast, HIV-negative PEL is usually EBV-negative. KSHV-associated MCD, although much more common in HIV-infected populations, also occurs in the general population.

MCD is a nonclonal lymphoproliferative disorder typically involving the mantle zone of lymph nodes and the spleen.[47] MCD can be a KSHV-associated or idiopathic, without detectable KSHV. In KSHV-associated MCD, the virus appears to drive λ light chain rearrangement in the lymphocytes that give rise to Castleman disease.[48] These cells express a broad range of KSHV lytic antigens, and high KSHV copy numbers are present in blood. Evolution into or coassociation with an aggressive lymphoma, often of plasmablastic phenotype, is not uncommon. Within the HIV population, nearly all cases of MCD are KSHV-associated; this viral association is not as strong among HIV-negative MCD patients. High expression of viral interleukin-6 (IL-6) is thought to contribute to the systemic inflammation seen in this disorder.[49] The KSHV-associated lymphomas that arise in association with MCD are not nodal equivalents of PEL; rather, these plasmablastic lymphomas (see E-Slide VM03957) are uniformly EBV-negative and express IgM λ.[50]

Diagnostic and Therapeutic Considerations

The characteristic finding in PEL is a lymphomatous effusion, which can be pleural, pericardial, or peritoneal, without associated lymphadenopathy or masses, arising in the setting of immunocompromise.[45] Often, patients with HIV/AIDS will present with PEL in addition to other KSHV-associated diseases, such as Kaposi sarcoma and MCD, so thorough evaluation and staging should be undertaken at diagnosis. On cytologic examination, the PEL tumor cells are large with prominent nucleoli. The effusion cells are clonal B cells with CD45 positivity but typically lack other specific B-cell lineage markers, although CD30 and CD38 positivity can be seen. B-cell lymphoma 6 (BCL6) mutations are frequently detected. Tumor cells always harbor KSHV, as demonstrated by staining for KSHV-associated latency-associated nuclear antigen-1. In MCD, there is characteristically λ light chain restriction. This does not reflect clonality as assessed by study of immunoglobulin DNA rearrangements. Rather, it reflects a tendency for the virus to selectively drive B lymphocytes to proliferate and induce immunoglobulin class switching.[51]

Treatment of PEL is most commonly combination chemotherapy and outcomes remain poor. Treatment of KSHV-associated MCD has been more successful with rituximab alone or in combination with chemotherapy.[47] Antivirals such as ganciclovir and valganciclovir have shown clinical activity in MCD because viral lytic replication is a feature of this disease.[52] Tocilizumab, an IL-6 receptor antibody, has transient activity in KSHV-associated MCD, but siltuximab, an antibody IL-6, has not been studied due to concerns that it will not bind to viral IL-6.[53]

HUMAN T-LYMPHOTROPIC VIRUS-1

Viral Biology

HTLV-1 is a retrovirus with a single-stranded RNA genome. Following infection there is reverse transcription and integration of proviral DNA into the host genome. HTLV-1 infects a variety of cell types but persists in the subset of CD4$^+$ T lymphocytes that are regulatory T cells.[54] Viral infection within the host is spread from cell to

Figure 87.4 HUMAN T-LYMPHOTROPIC VIRUS-1 (HTLV-1) AND THE EVOLUTION OF ADULT T-CELL LEUKEMIA/LYMPHOMA. Following HTLV-1 infection, many cells undergo apoptosis, but some infected CD4$^+$ T cells are driven to proliferate by the effects of Tax on the nuclear factor-κB (NFκB) pathway and on the AKT pathway. Tax is also suggested to result in inactivation of p53, aneuploidy, and deoxyribonucleic acid (DNA) damage. Over many decades, malignancy evolves.

cell through direct cell-to-cell contact. As with EBV, the proliferation of HTLV-1–infected lymphocytes plays a central role in ensuring viral persistence.

The HTLV-1 protein Tax is also a mediator of immune dysregulation, T-lymphocyte immortalization, and transformation (Fig. 87.4).[55] Tax affects NFκB and the serine/threonine kinase protein kinase B (AKT) pathways with diverse proliferative and antiapoptotic effects. As with some of the immunodominant EBV antigens expressed in proliferating lymphocytes, Tax expression is targeted by cytotoxic T cells. Another viral protein, Hbz, suppresses Tax expression, allowing transformed T cells to elude immune surveillance. Tax interferes with various DNA repair pathways and induces reactive oxygen species, facilitating the development of aneuploidy.[56] Tax leads to functional inactivation of p53 and may interfere with the spindle assembly checkpoint that normally operates in mitosis to preserve euploidy.

Epidemiology of Viral Infection and Adult T-Cell Leukemia/Lymphoma

HTLV-1 is endemic in particular regions of Japan, Africa, South America, and some Caribbean islands.[57] As assessed by seroprevalence, rates up to 37% are found on the southwestern Japanese islands of Shikoku, Kyushu, and Okinawa, whereas most other areas of Japan have an intermediate prevalence of 1% to 5%. In the United States, the incidence in blood donors is 0.025%. It has been estimated that about 20 million individuals are infected worldwide. The major mode of transmission in endemic areas is from mother to child in breast milk, although infection is also transmitted through sexual intercourse, transfusion of cellular blood products, and the sharing of needles and syringes. Evidence has been presented that HTLV-1 infection persists in association with certain human leukocyte antigen (HLA) types and may be more readily transmitted from mother to child when these HLA types are shared.

Adult T-cell leukemia (ATL) is more common in men than in women and typically presents in the fourth or fifth decade of life. Perhaps as a function of the long latency period, cases of ATL following blood transfusion or needle sharing are vanishingly rare. The lifetime risk for ATL has been estimated to be in excess of 6% in men who are HTLV-1 carriers in an endemic region of Japan, although in other settings the risk may be much lower.[58] As with EBV, the subset of the infected population that develops lymphoma is quite small.

Adult T-Cell Leukemia/Lymphoma Diagnostic Considerations

There is a spectrum of ATL. In the acute leukemic subtype of ATL, comprising around 60% of cases, leukocytosis, diffuse lymphadenopathy, and hypercalcemia are common. The classic findings on a peripheral blood smear are lymphocytes with flower-shaped nuclei (see Fig. 87.3C). Twenty percent of patients with ATL present with a lymphomatous subtype dominated by lymphadenopathy and hepatosplenomegaly. Cutaneous infiltration, lytic bone lesions, malignant effusions, and involvement of the CNS and other extranodal sites are not uncommon.[59] There are also chronic and smoldering subtypes that behave much more indolently and may not even require treatment upon diagnosis. Across all subtypes, presentations reflecting immune dysfunction such as strongyloidiasis with dissemination, *Pneumocystis jiroveci* pneumonia (PJP), mycobacterium, or cryptococcal infection are common. The immune dysfunction seen in patients with ATL may be due to the fact that the leukemic cells have a regulatory T-cell phenotype that fosters an immunosuppressive environment.

Histologically ATL shows lymph node effacement by large, atypical T cells usually expressing $CD4^+$, $CD25^+$, and $CD52^+$, with variable CD30 and CD15 expression. Aneuploidy is consistent, although characteristic cytogenetic abnormalities have not been identified. Serologic analysis confirms the presence of HTLV-1 infection.[60]

Therapies Specific to Human T-Lymphotropic Virus-1 Adult T-Cell Leukemia

Smoldering and favorable chronic-type variants of ATL may initially be observed, offered skin-directed therapies, or given a trial of antivirals. Several antivirals used in the treatment of HIV infection have activity against HTLV-1. Zidovudine and IFN can be used in smoldering, chronic, or leukemic subtypes, but patients with lymphoma-type ATL do not benefit from this combination.[61,62]

The leukemic and lymphomatous forms of ATL are aggressive and are associated with poor responses to chemotherapy, high relapse rates, and low overall survival. There is a 10% to 20% risk of CNS involvement, and all patients should receive CNS prophylaxis. Various combinations of chemotherapy are used depending on local availability.[63] The humanized anti–CC chemokine receptor 4 antibody, mogamulizumab, is approved in Japan, but is associated with increased mortality when given days to weeks prior to allogeneic hematopoietic stem cell transplantation.[64,65] Importantly, transplantation is increasingly being used in the front-line setting.[66,67] Brentuximab vedotin with combination chemotherapy has recently been included for treatment of CD30+PTCL, including ATL.[68] The PD-1 inhibitor nivolumab appears to lead to rapid progression of disease although only 3 patients were enrolled in a cooperative group trial.[69]

Several other agents have shown activity in the recurrent or refractory setting based on limited data: lenalidomide, proteasome and histone deacetylase inhibitors, alemtuzumab, an anti-CD52 monoclonal antibody, arsenic trioxide combined with IFN-α, all-*trans* retinoic acid, and pralatrexate.[70,71]

HUMAN IMMUNODEFICIENCY VIRUS-ASSOCIATED LYMPHOMAS

Viral Biology and Pathogenesis

HIV-1 is a retrovirus that infects $CD4^+$ T cells and monocytes. It establishes a lifelong reservoir in $CD4^+$ T cells. Viral infection may lead to cell death or establishment of latency in resting cells. The lymphomas that are increased in HIV-infected patients (see Table 87.4) are of B-cell lineage, and many are associated with EBV, KSHV, or both (see Table 87.4).

HIV infection compromises cellular immunity, decreasing immune surveillance of EBV- and KSHV-infected B cells.[72] In addition, HIV infection stimulates proliferation of B lymphocytes and perhaps genetic aberrations in the proliferating cells.[73] Many possible mechanisms have been invoked, including direct stimulation of B cells by HIV antigens or antigens associated with opportunistic infection; (2) stimulation of B cells by cellular proteins (CD40 ligand) incorporated into the HIV virion, leading to expression of activation-induced deaminase, an enzyme that mediates double-stranded DNA

TABLE 87.4 **Human Immunodeficiency Virus–Associated Lymphoma**

Lymphoma	CD4 Association (cells/mm^3)	EBV Association (%)	Other Cofactors
PCNSL	<50	>95%	
DLBCL	Variable	40%	
BL	>100	30%	
HL	>100	90%	
PEL	<100	>75%	KSHV

BL, Burkitt lymphoma; *DLBCL*, diffuse large B-cell lymphoma; *EBV*, Epstein-Barr virus; *HIV*, human immunodeficiency virus; *HL*, Hodgkin lymphoma; *KSHV*, Kaposi sarcoma–associated herpesvirus; *PCNSL*, primary central nervous system lymphoma; *PEL*, primary effusion lymphoma.

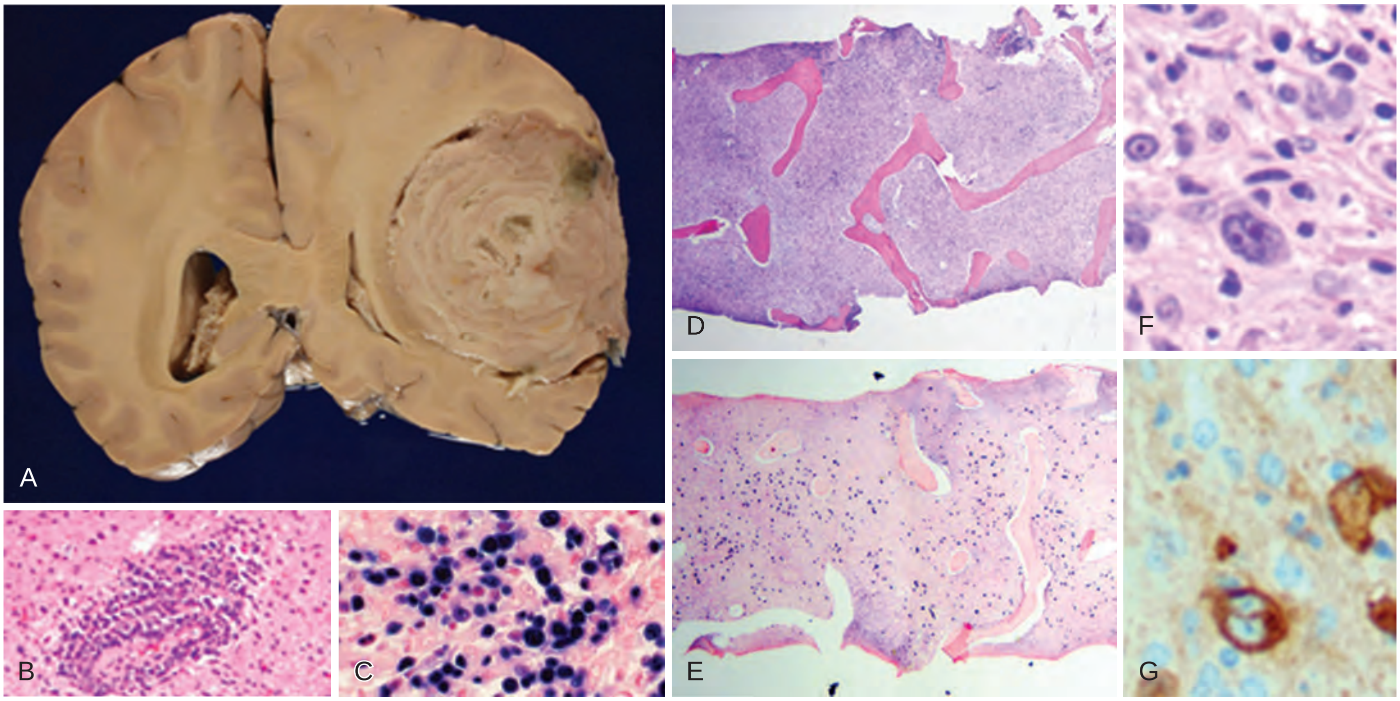

Figure 87.5 EXAMPLES OF HUMAN IMMUNODEFICIENCY VIRUS (HIV)–RELATED LYMPHOMAS. Primary central nervous system (CNS) lymphoma in HIV-positive patients (A–C). Gross appearance (coronal section) of the brain from an autopsy of a 24-year-old HIV-positive female patient with temporoparietal mass due to a primary CNS lymphoma (A). The patient died as a result of uncal and cingulate herniation. (B) Biopsy section from another patient showing a perivascular infiltrate of large lymphoma cells. This is the typical pattern of involvement by CNS lymphoma. The cells were shown to be CD20$^+$ B cells and were EBER-positive (C). A diagnosis can be made without biopsy when magnetic resonance imaging studies show characteristic features and EBV is demonstrated in the cerebrospinal fluid by polymerase chain reaction (see box on AIDS Primary Central Nervous System Lymphoma). Hodgkin lymphoma extensively involving the bone marrow in an HIV-positive patient with stage IVB disease (D–G). The bone marrow biopsy was entirely replaced with Hodgkin lymphoma associated with dense sclerosis (D). An EBER study shows scattered positive cells throughout the marrow (E), corresponding to the Hodgkin and Reed-Sternberg cells (F), which were CD30$^+$ as illustrated (G). Hodgkin lymphoma infrequently involves the bone marrow in HIV-negative cases, but some HIV-positive patients can first present with extensive bone marrow disease (see box on HIV Associated Hodgkin Lymphoma). *(A, Courtesy Dr. Peter Pytel, University of Chicago.)*

AIDS PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

In AIDS PCNSL, EBV PCR of the cerebrospinal fluid is positive approximately 90% of the time and rarely positive in patients with AIDS but without PCNSL. When EBV is detected in the cerebrospinal fluid of a patient with AIDS, coupled with characteristic magnetic resonance imaging findings, this is sufficient to diagnose AIDS PCNSL without a confirmatory brain biopsy.

HIV-ASSOCIATED HODGKIN LYMPHOMA

A 42-year-old HIV-positive patient, on highly active ART with a CD4 count of 324 cells/mm^3 and undetectable viral load, presents with fever, weight loss, and a palpable axillary lymph node. HL is diagnosed on excisional biopsy, and EBV positivity is demonstrated by EBER in the Reed-Sternberg tumor cells. Although he lacks additional lymphadenopathy, a bone marrow biopsy is performed, and it shows involvement by HL. He has stage IVB disease. *Pneumocystis jiroveci* pneumonia prophylaxis is started despite an adequate CD4 count in anticipation of chemotherapy. His ART regimen is reviewed for potential antiviral-chemotherapy drug interactions. He receives six cycles of full-dose, first-line chemotherapy and achieves a complete remission.

breaks; and (3) dysregulation of B cells as a consequence of T-cell dysfunction. There is also some evidence that host biology may contribute to lymphomagenesis.[74]

Epidemiology

Lymphoma is increased in all HIV risk groups, in contrast to Kaposi sarcoma, which is rarely seen in injection drug users (or in hemophiliacs in an earlier era).[75] There is a well-established relationship between CD4$^+$ cells per cubic millimeter overall and the risk for lymphoma, but the relationship is complex and differs among lymphomas (Table 87.4).

The incidence of non-Hodgkin lymphoma (NHL) in the HIV population, particularly PCNSL (Fig. 87.5A–C), has decreased with the widespread use of highly active antiretroviral therapy (ART). However, the incidence of HL has not declined.[76] CD4$^+$ counts can help guide evaluation insofar as CD4$^+$ counts greater than 300 cells/mm^3 are typically associated with BL or HL, whereas these diagnoses would be unlikely in patients with CD4$^+$ counts less than 50 cells/mm^3 (see box on AIDS Primary Central Nervous System Lymphoma).[77,78]

Patients with HIV are now living much longer because of effective antiretroviral regimens and decreased rates of opportunistic infection. As a result, malignancy has emerged as the major cause of mortality in HIV populations with access to antiretroviral therapy.[79,80]

Diagnostic Considerations Specific to Lymphoma in Patients With Human Immunodeficiency Virus

Lymphomas in patients with HIV infection are more likely to present with B symptoms. Therefore, unexplained fever and sweats, even in the absence of lymphadenopathy, are sufficient to warrant consideration of HL. Bone marrow–only presentations of

HL are not uncommon, and contiguous spread so characteristic of classic HL in other settings is less common in HIV HL (see Fig. 87.5D–G). Patients with HIV-associated NHL have higher rates of extranodal involvement, including bone marrow and CNS disease, as well as higher-stage disease and more aggressive tumors on average.[81] All HIV-seropositive patients with aggressive NHL should undergo a diagnostic lumbar puncture. Imaging must be interpreted with caution because metabolically active lymph nodes on positron emission tomography–computed tomography (PET-CT) may represent HIV infection itself, opportunistic infection, immune reconstitution following the initiation of antiretroviral therapy, or lymphoma.

Therapy

Prior to effective antiretroviral therapy, HIV patients experienced increased mortality from chemotherapy due to their underlying immunocompromised state.[82] However, with ART and the advancement of supportive care, dose-reduced chemotherapy is no longer standard practice.[83,84] Dose reductions can be considered with low $CD4^+$ count (<100 cells/mm^3), history of ongoing opportunistic infection, performance status below 75%, or compromised organ function. There is general agreement that the inclusion of rituximab with multiagent chemotherapy improves outcomes, at least in patients with $CD4^+$ counts of greater than 50 cells/mm^3.[85,86]

Antiretroviral Therapy

A few key special issues in considering concurrent antiretroviral and lymphoma therapy include concerns about shared toxicities, drug–drug interactions, and risk for inability to comply with consistent antiretroviral dosing. Antiretrovirals that interact with the cytochrome P-450 CYP3A4 pathway are of particular concern due to multiple drug-drug interactions and modification of ART may need to be considered. Collaboration with HIV or oncology pharmacists is recommended. In addition, nausea and vomiting associated with chemotherapy may interfere with regular antiviral dosing, which raises the concern for the development of a resistant strain of HIV.[87] Trials have demonstrated that patients continued on their previously established antiretroviral regimen during chemotherapy have acceptable outcomes and more rapid immune reconstitution after chemotherapy compared with those not on antiretrovirals.[88,89] Clinicians should only hold ART during chemotherapy when alternative ART regimens without drug interactions are not available.

Supportive Care

Although PJP prophylaxis is recommended only when the $CD4^+$ count is less than 200 cells/mm^3 for patients with HIV not receiving cytotoxic chemotherapy, prophylaxis is often universally used for patients with HIV receiving cytotoxic chemotherapy. The following are also commonly used: fungal prophylaxis with fluconazole; herpes simplex and varicella prophylaxis with acyclovir, valacyclovir, or famciclovir; quinolone prophylaxis when neutrophil counts fall below 1000 cells/mm^3; and granulocyte growth factors.

Bone Marrow Transplant in Patients With Human Immunodeficiency Virus

Autologous bone marrow transplant has been successful in HIV-seropositive patients with NHL, with these patients having adequate stem cell mobilization, nonrelapse mortality rates comparable to those for HIV-negative patients, count recovery within 2 weeks of stem cell rescue, and maintained control of HIV viral loads and $CD4^+$ counts after high-dose chemotherapy[90] (see box on Autologous Bone Marrow Transplant in an HIV-Seropositive Hodgkin Lymphoma Patient). There have also been successful reduced-intensity allogeneic bone marrow transplants in HIV-seropositive patients.[91,92] The first national trial of allogeneic bone marrow transplant for patients with HIV and hematologic malignancy demonstrated the safety and efficacy of transplantation for all HIV-positive patients who otherwise meet standard inclusion criteria.[93] The role of transplant in curing HIV is an area of active investigation, including cell engineering strategies to render cells resistant to HIV.[94,95] To date, there have been two patients who obtained sustained viral remissions after CCR5Δ32 homozygous hematopoietic stem-cell transplant.[96–98]

AUTOLOGOUS BONE MARROW TRANSPLANT IN AN HIV-SEROPOSITIVE PATIENT WITH HODGKIN LYMPHOMA

A 38-year-old HIV-positive patient with a $CD4^+$ count of 485 cells/mm^3 is diagnosed with classic Hodgkin lymphoma (HL) and treated with doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD), achieving a complete remission. Two years later he presents with retroperitoneal lymphadenopathy and is found on biopsy to have relapsed HL. He is treated with salvage chemotherapy and has a complete response, as well as good performance status and no active infections. His HIV remains well controlled on antiretroviral therapy. He is deemed an excellent candidate for high-dose therapy and undergoes consolidation with autologous bone marrow transplant.

HEPATITIS C VIRUS

Viral Biology and B-Lymphocyte Proliferation

HCV is an enveloped, positive-stranded RNA virus.[99,100] Infection involves interactions between E2, a viral structural protein with two hypervariable regions, and a cellular protein CD81 present on hepatocytes and B lymphocytes. A polyprotein is translated from viral RNA and is cleaved by cellular and viral proteases, including NS3, to yield proteins required for viral replication. The RNA-dependent RNA polymerase that replicates the viral genome lacks proofreading capacity, thus generating genetic heterogeneity among viral progeny. Viral replication occurs predominantly in hepatocytes, but viral RNA and NS3 have also been detected in B cells, although HCV replication in B cells remains controversial.[101]

Chronic infection can be associated with mixed cryoglobulinemia, a systemic immune disease that results from clonal expansion of B cells producing an IgM autoantibody against IgG, leading to deposition of immune complexes on endothelial surfaces and resulting in inflammation.[102] In this setting of B-cell proliferation, some patients develop B-cell NHL, which is classically of low-grade histology. Several hypotheses have been advanced with regard to how HCV might drive B-cell proliferation. There is controversy as to whether infection of B cells plays any role in this process.[103] A lymphoma cell line that produces infectious HCV has been reported. Even in the absence of infection of B cells, interaction of the HCV E2 protein with CD81 on B cells may drive B-cell proliferation or lower the threshold for other B-cell stimuli to drive proliferation. Immunoglobulin signaling may be activated by immunoglobulin-virus complexes, and Toll-like receptor 7 signaling may be activated by viral RNA. Finally, it is noted that E2 binding triggers expression of activation-induced deaminase, an enzyme that is important in generating somatic hypermutation and that has also been implicated in mediating mutations thought to play a role in DLBCL lymphomagenesis.[104]

Epidemiology of Viral Infection and Associated Lymphoma

In systematic reviews, approximately 13% to 18% of B-cell lymphomas are associated with HCV infection.[105–107] Most commonly, these lymphomas are histologically indolent subtypes, with splenic marginal zone lymphoma (MZL), nongastric MALT, and lymphoplasmacytic lymphoma more often seen in association with HCV than aggressive histologies such as DLBCL.[108–110] The HCV–lymphoma association is more apparent in some countries than in others, with the association being established most clearly in Italy, Taiwan, and Japan. Several studies in regions or countries where HCV infection is less prevalent have failed to identify any association with lymphoma.[111–114] In the United States, there is a small but significant increase in B-NHL risk with HCV infection.[115,116]

Further evidence in support of an etiologic relationship comes from studies in which successful treatment of HCV was followed by lymphoma regression.[117] Furthermore, clearance of HCV infection has been shown to reduce the incidence of B-NHL, with cumulative incidence of lymphoma among patients with a sustained virologic response of 0% at 15 years, as compared with 2.6% at 15 years among both nonresponders and untreated patients.[118]

Diagnostic and Prognostic Considerations

In contrast to EBV-, KSHV-, or HTLV-1-associated tumors, there is no established role for studies demonstrating HCV nucleic acid or protein in tumor cells. An HCV prognostic score comprised of poor performance status, hypoalbuminemia, and high HCV-RNA viral load effectively risk stratified patients with DLBCL into three groups with significantly different progression-free and overall survival outcomes.[119]

Therapy

In patients with indolent lymphomas and untreated HCV infection, antiviral treatment may obviate the need for cytotoxic chemotherapy and should be considered as an initial therapeutic strategy.[117,120]

Rituximab has been associated with rises in HCV viral load and increased rates of hepatotoxicity, and there is the possibility that elimination of B cells for several months following treatment may compromise humoral responses to the evolution of HCV quasispecies. However, in studies to date, overall survival is not inferior.[119,121] Unlike in cases of indolent lymphoma, where antiviral therapy alone may be sufficient, rituximab-containing multiagent chemotherapy regimens are recommended for HCV-associated DLBCL. Concomitant treatment with direct acting antivirals is safe and effective.[122]

FUTURE DIRECTIONS

In this chapter, a variety of virus-associated lymphomas and lymphoproliferative diseases have been reviewed. For most of these lymphomas, standard antiviral drugs do not have a role in treatment. There are several exceptions, however, and these are worth highlighting. Antiviral therapy for HCV-associated splenic lymphoma with villous lymphocytes is accepted as a standard approach and likely has a role in the treatment of other HCV-associated indolent lymphomas. Similarly, ganciclovir or valganciclovir may have a role in the management of MCD associated with KSHV in patients with HIV. Of course, there is an established role for antiretroviral therapy in the treatment of patients with HIV and malignancy. There are virus-targeted therapies that are broadly accepted as standard, including adoptive immunotherapy with EBV-specific T cells for PTLD. The use of targeted T cells also has promise in other settings, including EBV-associated HL. Other virus-targeted therapies are being developed. Some involve vaccination; others involve induction of viral genes in tumor cells, rendering them more susceptible to pharmacologic treatment. Finally, it may ultimately be possible to prevent some kinds of lymphoma by preventing viral infection or altering the host response to viral infection.

CHAPTER 88

MALIGNANT LYMPHOMAS IN CHILDHOOD

Kara M. Kelly, Birgit Burkhardt, and Catherine M. Bollard

Malignant lymphomas are the third most common malignancy among children and adolescents.[1–3] Among children less than 15 years of age, non-Hodgkin Lymphoma (NHL) is more frequent; however, in patients up to 18 years of age, Hodgkin lymphoma (HL) is predominant. NHLs in children are usually extranodal diffuse high-grade tumors, whereas low- and intermediate-grade nodal lymphomas predominate in adults. These differences are speculated to reflect maturational changes in the function and composition of the immune system.[2] The different histologies explain in part the differing clinical features, disease course, and treatment strategies used in adults and children.

The differences in treatment approach and disease subtypes are less striking in adults and children with HL. However, there are significant challenges in the management of children with HL. These primarily comprise the sequelae of therapy, such as radiation-induced bone growth abnormalities, endocrine dysfunction, and chemotherapy-related sterility. Of greater concern are the radiation- and chemotherapy-related second malignancies and late cardiac deaths. Current trials are examining ways to reduce the toxicity of therapy without compromising the excellent outcome generally achieved.

NON-HODGKIN LYMPHOMA

Epidemiology

The incidence of NHL increases steadily throughout life, in contrast to Hodgkin disease, which has a bimodal age distribution peaking in early and late adulthood.[2] Although NHLs may occur at any age in childhood, they are infrequent among children younger than 3 years of age; the median age at presentation is approximately 10 years. NHL is two to three times more frequent in boys than in girls and is almost twice as common in Whites as in African Americans—the reasons for these differences have yet to be determined.[4]

Specific populations at risk for the development of NHL include those with either congenital or acquired immunodeficiency conditions.[5] Inherited immunodeficiency syndromes include Wiskott-Aldrich syndrome, X-linked lymphoproliferative syndrome (XLP), and ataxia-telangiectasia (AT).[6] The recognition of these syndromes in children with newly diagnosed NHL is important for appropriate therapeutic design. For example, involved field irradiation and radiomimetics should be avoided in children with AT. Additionally, children with AT are at increased risk for the development of cyclophosphamide-induced hemorrhagic cystitis; therefore, they should receive vigorous hydration and uroprotectants (e.g., Mesna) when administering any dose of cyclophosphamide. XLP should be considered in any male with a high-grade B-cell lymphoma who either develops a late recurrence (second occurrence) of a high-grade B-cell lymphoma or has a brother with either a high-grade B-cell lymphoma or fatal infectious mononucleosis. Children with acquired immunodeficiency conditions predisposing to the development of NHL include those who have received post-transplant immunosuppressive therapy and those with acquired immunodeficiency syndrome (AIDS).

There are differences in both the incidence and proportion of histologic subtypes in distinct parts of the world. For example, the NHLs are rare in Japan but occur quite frequently in equatorial Africa. Burkitt lymphoma, which accounts for about one-half of all childhood cancers in equatorial Africa, is the predominant NHL histologic subtype in both equatorial Africa and northeast Brazil.[7] There are also geographic differences in both the clinical and biologic features of certain NHL subtypes.[8,9]

Classification

After Thomas Hodgkin described the disease bearing his name in 1832, various schemes emerged to classify the tumors now collectively referred to as the NHLs. Several classification schemes were developed based on histopathologic features and the putative cell of origin. In an attempt to reduce the confusion of multiple classification schemes, the National Cancer Institute (NCI) sponsored a workshop to design a single classification scheme for clinical usage. This scheme published in 1982 and referred to as the NCI Working Formulation was widely accepted for almost two decades. In the Working Formulation, the NHLs of childhood are predominantly diffuse high-grade tumors and can be divided among three major subgroups: lymphoblastic, small noncleaved cell, and large cell lymphomas.

In the past decade, additional classification schemes were designed to improve upon the NCI Working formulation. Because of the problems associated with attempts to classify lymphoid neoplasms into categories based on presumed normal cell counterparts, the International Lymphoma Study Group proposed a classification system for lymphoid neoplasms[10] predicated on a practical approach to categorizing these diseases using available immunologic and molecular genetic techniques in addition to the standard morphologic criteria. This Revised European-American Classification of Lymphoid Neoplasms (REAL Classification) has been endorsed by many of the world's leading lymphoma pathologists and has served as the basis for the World Health Organization (WHO) classification of hematopoietic and lymphoid tumors.[11] Both the REAL and WHO classification systems include related lymphoid leukemias and recognize that NHL and acute lymphoblastic leukemia (ALL) represent different stages of evolution within specific morphologically and immunologically defined disease categories—an observation recognized by clinicians caring for children with lymphoid neoplasms and reflected in current clinical practice which prescribes similar therapies for lymphomas and leukemias of related phenotype.

In the REAL and WHO classification systems, NHLs are classified based on phenotype (B-lineage versus T-lineage versus natural killer (NK) cell lineage) and differentiation (precursor vs. mature). Hence, NHLs that occur commonly in children appear in three major categories: Lymphoblastic lymphoma (LBL; precursor B-cell lymphoma and precursor T-cell lymphoma), mature B-cell NHL (Burkitt and Burkitt-like lymphoma and diffuse large B-cell lymphoma [DLBCL]), and anaplastic large cell lymphoma (ALCL; mature T-cell or null-cell types). The current version of the WHO classification introduced pediatric follicular lymphoma, marginal zone lymphoma, and grey zone lymphoma.[10]

The clinical and biological characteristics of NHL in children are summarized in Table 88.1 and illustrated in Fig. 88.1A-C.

TABLE 88.1 Characteristics of Non-Hodgkin Lymphoma in Children

Subtype	Proportion of Cases in BFM Studies (%)[14]	Phenotype	Primary Site
Lymphoblastic	26	T-cell; B-cell	Mediastinum or head and neck; lymph nodes, skin, soft tissue, bone
Burkitt	49	B-cell	Abdomen or head and neck
DLBCL	13	B-cell	Lymph nodes, mediastinum, abdomen, head and neck
ALCL	13	T-cell indeterminate	Mediastinum, abdomen, head and neck, bone, soft tissue, or skin

ALCL, Anaplastic large cell lymphoma, *BFM*, Berlin-Frankfurt-Münster; *Ig*, immunoglobulin.

Lymphoblastic Lymphoma

Introduction

It is an ongoing discussion whether LBL and ALL are two clinical presentations of the same disease or two different diseases.[12,13] Patients with a mass and fewer than 25% bone marrow lymphoblasts are designated as LBL, whereas patients with at least 25% bone marrow involvement have ALL. In contrast to ALL, more than 75% of LBL demonstrate a precursor T-cell immunophenotype (T-LBL), with the remainder showing a precursor B-cell immunophenotype (pB-LBL).[14–16]

Epidemiology

LBL constitutes 22% to 28% of childhood NHL. There is a 2:1 male predominance for LBL, but the incidence of LBL remains constant across the pediatric age group for both boys and girls.[17]

Pathobiology

LBL arises from precursor T- or B-lymphoblasts at varying stages of differentiation. Morphology is similar to that of ALL, with lymphoblasts of small or medium size and with scant cytoplasm, round or convoluted nuclei, fine chromatin, and indistinct or small nucleoli. Immunophenotyping shows terminal deoxynucleotidyl transferase (TdT) positivity. T-LBL is usually positive for CD7 and surface or cytoplasmic CD3, with variable expression of CD2, CD5, CD1a, CD4, and CD8.[18] Stains for TdT, CD3, MPO, and a B-cell marker like pax5 or CD79a are recommended parts of a resource-saving diagnostic staining panel.[19] CD10 expression is more frequent in T-LBL (40%) than T-ALL (less than 10%), possibly related to the maturational stage, with T-ALL more frequently demonstrating an immature phenotype.[16,20,21] B-lineage markers are positive in B-LBL. Similar to ALL, cases with mixed phenotypes are reported but interestingly not associated with inferior outcome.[22] Unlike ALL, there are no known cytogenetic prognostic factors for LBL. Recurrent cytogenetic anomalies are seen in about half of childhood T-ALL but have not been well-defined in T-LBL. Literature is scarce regarding typical chromosomal aberrations for T-LBL.[23] The commonest chromosomal translocations for both T-LBL and T-ALL involve the T-cell receptor (*TCR*) gene loci at chromosome 14q11 or 7q34. Certain molecular genetic alterations were analyzed in relevant patient series of pediatric T-LBL including *NOTCH1*, *FBXW7*, *PTEN* alterations, PIM1 variants, alterations of chromosome 9p containing *CDKN2A/CDKN2B* loci, and chromosome 6q.[24–28] A recent targeted sequencing study of a relevant series of pediatric T-LBL confirmed *NOTCH1* as the putative driver for T-LBL resulting in an activated NOTCH/PI3K-AKT signaling axis. In addition, alterations in cell cycle regulators constitute the core oncogenic program for T-LBL. The mutational status of *KMT2D* was identified as a prognostic marker. The ongoing international clinical trial LBL 2018 (NCT04043494) introduced a

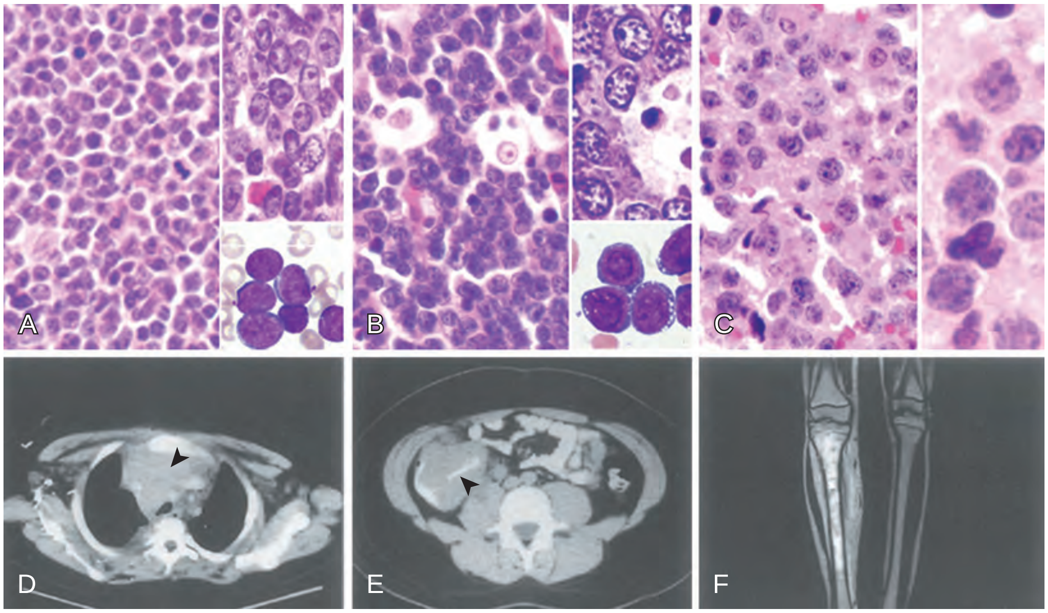

Figure 88.1 HISTOLOGIC AND CLINICAL FEATURES OF THE NON-HODGKIN LYMPHOMAS OF CHILDHOOD. The upper panels demonstrate the appearance in the H&E section of Burkitt lymphoma (Panel A); lymphoblastic lymphoma (Panel B); and anaplastic large cell lymphoma (Panel C). The inserts in Panels A and B demonstrate the appearance of Wright's stained specimens of the L3 blasts of Burkitt lymphoma and the L1 blasts of lymphoblastic lymphoma, respectively. The lower panels show common clinical presentations of the two histologic subtypes of lymphoma: airway compression by lymphoblastic lymphoma of the anterior mediastinum on computed tomography of the chest (Panel D) and encasement of the bowel lumen by Burkitt lymphoma on abdominal computed tomography (Panel E). *(Reproduced, in part, from Sandlund JT, Downing JR, Crist WM, et al. Non-Hodgkin's lymphoma in childhood. N Engl J Med. 1996;334[19]:1238–1248.)*

TABLE 88.2 Murphy Staging of Non-Hodgkin Lymphoma

Stage	Criteria
Stage I	A single tumor (extranodal) or involvement of a single anatomic area (nodal), with the exclusion of the mediastinum and abdomen.
Stage II	A single tumor (extranodal) with regional node involvement.
	Two or more nodal areas on the same side of the diaphragm.
	Two single (extranodal) tumors, with or without regional node involvement on the same side of the diaphragm.
	A primary gastrointestinal tract tumor (usually in the ileocecal area), with or without the involvement of associated mesenteric nodes, that is completely resectable.
Stage III	Two single tumors (extranodal) on opposite sides of the diaphragm.
	Two or more nodal areas above and below the diaphragm.
	Any primary intrathoracic tumor (mediastinal, pleural, or thymic).
	Extensive primary intraabdominal disease.
	Any paraspinal or epidural tumor, whether or not other sites are involved.
Stage IV	Any of the above findings with initial involvement of the central nervous system, bone marrow, or both.

*Based on the classification proposed by Murphy SB, Fairclough DL, Hutchison RE, et al. Non-Hodgkin's lymphomas of childhood: an analysis of the histology, staging, and response to treatment of 338 cases at a single institution. *J Clin Oncol.* 1989;7(2):186–193.

TABLE 88.3 International Pediatric Non-Hodgkin Lymphoma Staging System

Stage	Criteria for Extent of Disease
I	A single tumor with exclusion of mediastinum and abdomen
II	A single tumor with regional node involvement
	≥2 nodal areas on the same side of the diaphragm
	A primary gastrointestinal tract tumor (usually in the ileocecal area), with or without involvement of associated mesenteric nodes, that is completely resectable (if malignant ascites or extension of tumor to adjacent organs, it should be regarded as stage III)
III	≥2 extranodal tumors (including EN-B or EN-S) above and/or below the diaphragm
	≥2 nodal tumors above and below the diaphragm
	Any intrathoracic tumor (mediastinal, hilar, pulmonary, pleural, or thymic)
	Intraabdominal and retroperitoneal disease, including liver, spleen, kidney, and/or ovary localizations, regardless of degree of resection (except primary gastrointestinal tract tumor [usually in ileocecal region] and/or involvement of associated mesenteric nodes that is completely resectable)
	Any paraspinal or epidural tumor, regardless of whether other sites are involved
	A single bone lesion with concomitant involvement of extranodal and/or non-regional nodal sides
IV	Any of the above findings with:
	Initial involvement of CNS (stage IV CNS)
	Initial involvement of the bone marrow (stage IV BM)
	Initial involvement of CNS and bone marrow (stage IV combined) based on conventional methods

B, Bone; *BM*, bone marrow; *EN*, extranodal; *N*, nodal; *S*, skin; *EN-B*, extranodal bone; *EN-S*, extranodal skin.

new stratification system taking into account the mutational status of *NOTCH1* and *FBXW7*. In parallel, the trial will allow prospective systematic validation of the prognostic relevance of individual markers or marker combinations to be translated into future trials.

Clinical Manifestations

The clinical features at presentation vary with primary site and extent of disease spread. Almost all patients with T-LBL frequently present with an anterior mediastinal mass that may cause respiratory symptoms, airway compromise, dysphagia, or superior vena cava syndrome (see Fig. 88.1D). Pleural effusions are common (75%), and lymphadenopathy above the diaphragm is frequent. Bone, skin, bone marrow, central nervous system (CNS), abdominal organs, other lymph nodes, and occasionally testes may also be involved. Children with B-LBL are less likely to present with a mediastinal mass, but there is a higher frequency of cutaneous, soft tissue, or bone involvement with pB-LBL.[29–32] CNS involvement at diagnosis is seen in 4% to 5% of patients with LBL.[31,33]

Differential Diagnosis

LBL is distinguished from ALL by having less than 25% bone marrow involvement defined by cytomorphology of bone marrow smears and from myeloid malignancies being positive for TdT and T- or B-cell markers and negative for myeloperoxidase and additional myeloid markers. T-LBL and B-LBL are differentiated by flow cytometry or immunohistochemistry. In cases of insufficient biopsy material or incomplete diagnostic staining, LBL is sometimes misdiagnosed (e.g., as Ewing sarcoma or other small-, round-, blue-cell tumors).

Prognosis (Staging)

After obtaining malignant effusion or tissue diagnosis, staging is performed with imaging (ultrasound of the abdomen, lymph nodes and testes, and magnetic resonance imaging or computed tomography of involved sites), bilateral bone marrow evaluation, and lumbar puncture. Bone scans are only done if clinically indicated. Childhood NHL, including LBL, is most commonly staged using the Murphy classification previously and now by the International Pediatric Non-Hodgkin Lymphoma Staging System (IPNHLSS) (Table 88.2 and 88.3).[34,35]

With current therapies based on ALL protocols, LBL has a long-term survival greater than 90% in low-stage disease and greater than 80% in advanced-stage disease (Table 88.4).[36] The Children's Oncology Group demonstrated that minimal disseminated disease at diagnosis has prognostic value, as indicated by flow cytometric evidence of tumor cells in bone marrow.[37] The prognostic impact of minimal disseminated disease at diagnosis and minimal residual disease is under evaluation.[38–40] On NHL-BFM trials, adolescent females with T- LBL had poorer outcomes than adolescent males despite similar presenting characteristics.[41] One adult study for T-cell ALL has demonstrated poorer outcomes in females than males,[42] but a prognostic impact of gender has not been found in other pediatric or adult studies for LBL. While adolescent age itself has not been established as a poor prognostic factor as it has for ALL, adult outcomes for LBL are inferior to pediatric outcomes.[43]

Therapy

Two potentially life-threatening situations requiring urgent intervention must be considered in children with LBL: (1) mediastinal tumor with airway obstruction or superior vena cava syndrome, and (2) tumor lysis syndrome. Due to the cardiac and respiratory risks of anesthesia or sedation in children with a large mediastinal mass, the least invasive procedure should be chosen to establish a diagnosis. In children with relevant pleural effusion, pleural puncture and morphologic combined with immunologic diagnostics by

flow cytometry allow adequate diagnosis. In children with peripheral lymphadenopathy, lymph node biopsy under local anesthesia may be possible. In children who cannot tolerate a procedure, pretreatment with steroids may be necessary to stabilize the patient. Since pretreatment may diminish the ability to accurately diagnose a patient, a tissue diagnosis should be obtained as soon as it is possible to do so safely. Tumor lysis syndrome is characterized by metabolic consequences of the breakdown of lymphoma cells, causing renal failure if severe. Hyperuricemia, hyperkalemia, and hyperphosphatemia must be aggressively managed by hyperhydration, rasburicase and/or allopurinol, and close monitoring. Children with NHL can also present with epidural masses and associated neurologic deficits caused by spinal cord compression. If the diagnosis is known, chemotherapy should be started as soon as possible. If the diagnosis is not known, or if there is a sluggish response to chemotherapy, low-dose radiation therapy may be considered in consultation with a radiation oncologist.

ALL treatment strategies achieved favorable outcomes in LBL and are accepted as standard treatments as (e.g., the Berlin-Frankfurt-Münster [BFM]) combination chemotherapy with induction, consolidation, and maintenance phases lasting a total of 24 months with 90% 5-year event-free survival (EFS).[36] Even patients with stage III and IV LBL had good outcomes on ALL-type therapy.[44,45] This ALL-like therapy has now become standard for LBL (see Table 88.4).[46] CNS prophylaxis is needed for LBL, but chemotherapy prophylaxis has not proven inferior to prophylactic cranial irradiation in CNS-negative patients, even with advanced-stage disease.[28,31,47] Additionally, recent studies did not demonstrate a survival advantage of high-dose methotrexate for T-LBL.[45,48] Unfortunately, outcome is still poor for patients suffering LBL relapse.[49]

Burkitt Lymphoma

Introduction

Burkitt lymphoma (BL) was first described by Dennis Burkitt in the 1950s in Uganda.[50] First thought to be endemic to equatorial Africa, it was subsequently observed in Europe and North America. The WHO classification recognizes three variants: (1) sporadic BL, occurring throughout the world and more common in children, adolescents, and young adults; (2) endemic BL, occurring primarily in sub-Saharan Africa and New Guinea, with some unique clinical features but morphologically identical to sporadic BL; and (3) immunodeficiency-associated BL, observed primarily in HIV patients and less commonly in the setting of other immunodeficiencies. Burkitt-like lymphoma with 11q aberration is introduced as a provisional lymphoma entity in the 2017 revision of the WHO classification.[51] When there is marrow involvement of more than 25%, it is designated Burkitt leukemia (FAB L3 leukemia) but is treated similarly to BL.[10,11]

Epidemiology

Sporadic BL constitutes approximately 50% of childhood NHL and is much more common in boys than girls (ratio 4:1), with a peak incidence between 5 and 14 years of age.[14,17] Endemic BL associated with Epstein-Barr virus (EBV) in more than 85% of cases accounts for approximately half of all childhood cancers in equatorial Africa. In contrast, sporadic BL is most common in the United States and Europe and is associated with EBV in only 10% to 15% of cases.[52,53]

Pathobiology

BL is composed of monomorphic, small, noncleaved cells with round nuclei, clumped chromatin, and basophilic cytoplasm. A high uniform proliferation index is seen, with the Ki-67 positivity approaching 100%. The classic "starry sky" appearance of BL seen under low power microscopy is caused by tingible body macrophages scattered among malignant cells. BL cells show mature B-cell features and usually express surface immunoglobulins. B-cell markers such as CD19, CD20, and CD22 are usually present, and the majority express CD10 (common acute lymphoblastic leukemia antigen, CALLA). BL is negative for TdT and in most cases for B-cell lymphoma (BCL)-2. CD21, the EBV receptor, is more commonly seen in endemic BL than in sporadic BL.

Characteristic chromosomal translocations suggest that BL develops from genetic aberrations during somatic hypermutation or attempted immunoglobulin class switching. These translocations, usually t(8;14) or infrequently t(8;22) or t(2;8), juxtapose the c-*myc* gene (involved in cellular proliferation) with immunoglobulin locus regulatory elements, resulting in c-*myc* overexpression. In sporadic cases, the predominant chromosome 8 breakpoints usually occur within the c-*myc* gene, whereas they are upstream of the gene in endemic cases. For the rare event of *c-myc*-negative BL, characteristic aberrations of chromosome 11q characterized by interstitial gains including 11q23.2-q23.3 and telomeric losses of 11q24.1-qter were reported.[51,54] Other cytogenetic abnormalities, such as gain of 7q and deletion of 13q, are uncommon.[55,56] Recently published large-scale next-generation sequencing studies unveiled sets of recurrently mutated genes in tumor cells of pediatric and adult B-NHL patients and introduced functionally related inhibitor of DNA 3 (*ID3)*, transcription factor 3 (*TCF3)*, and cyclin D3 (*CCND3)* as potential drivers of BL lymphomagenesis.[35,57–59]

Clinical Manifestations

BL is an extremely fast-growing malignancy. The most common primary sites of sporadic BL are the abdomen and the lymph nodes of the head and neck.[60,61] Abdominal disease presentation often associated with nausea, vomiting, and abdominal pain carries a risk of intestinal perforation, obstruction, and gastrointestinal bleeding. Abdominal lymphoma often arises from the distal ileum causing intestinal obstruction secondary to intussusception or compression by an expanding mass encasing the bowel (see Fig. 88.1E). BL can involve lymph nodes, testes, bone, bone marrow, and CNS. CNS involvement at diagnosis occurring in about 9% of patients is associated with a worse outcome.[33] Endemic BL frequently involves the abdomen, jaw, paraspinal region, orbit, and CNS.

Differential Diagnosis

In DLBCL, another mature B-cell lymphoma, the cells are usually larger and less basophilic. Cytogenetic abnormalities such as BCL-6 gene rearrangements or t(14;18) may be seen in individual cases, although these abnormalities are more common in adult DLBCL. Ki-67 staining in less than 95% of the cells or positivity for BCL-2 are helpful in excluding a diagnosis of BL. TdT negativity is helpful in distinguishing BL from B-LBL. Recent studies addressed B-cell malignancies with immature phenotype but c-*myc* translocation. While biologically more closely related to ALL, treatment with BL regimen resulted in acceptable outcome.[62,63]

Prognosis (Staging)

The risk group classification developed by the French Society of Pediatric Oncology (SFOP) is widely used on current protocols incorporating risk-adapted therapy (Table 88.5). This system accounts for the adverse prognosis associated with CNS or bone marrow involvement and whether localized disease has been resected. Localized or CNS-negative advanced-stage BL have greater than 90% long-term survival with current therapies.[64] Combined CNS and BM involvement and suboptimal response to initial cytoreduction is also associated with worse prognosis, and poor responders are often stratified to more intensive chemotherapy on current regimens.[65] In recent trials, the French stratification system was extended by including LDH, as high LDH at diagnosis also carries a worse prognosis and is frequently incorporated in risk classification schemes (e.g., that of the BFM) (Table 88.6).[66] Age greater than 15 years has a worse outcome for mature B-cell malignancies, but this may be primarily due to DLBCL rather than BL. Recent studies on clonal evolution in BL underlined the prognostic role of *TP53* mutations.[36]

TABLE 88.5 French Society of Pediatric Oncology Risk Group Classification of Mature B-Cell Lymphomas

Group	Extent of Disease
Group A	Completely resected Stage I Completely resected abdominal Stage II
Group B	Nonresected Stage I and II Any Stage III CNS-negative Stage IV with BM involvement 5%–25%
Group C	CNS-positive Stage IV Stage IV with BM involvement ≥25% (mature B-cell ALL)

ALL, Acute lymphoblastic leukemia; *BM*, bone marrow; *CNS*, central nervous system; *SFOP*, French Society of Pediatric Oncology.

Therapy

Tumor lysis syndrome must be anticipated as a major risk in newly diagnosed BL or Burkitt leukemia. To help prevent this complication, children at risk should be vigorously hydrated. The urine pH should be maintained at about 7.0; at a more alkaline pH, phosphorus is less soluble, and at a more acidic pH, uric acid is less soluble. In some cases, furosemide is required to maintain urine output. Uricolytic agents (e.g., uricozyme), which have been used for many years in Europe, directly cleave the uric acid molecule and result in a precipitous drop in serum uric acid levels within a few hours. The use of uricolytic agents (e.g., urate oxidase, uricase, rasburicase) has proven to be superior to allopurinol to reduce rapidly the level of serum uric acid and improve renal function. Rasburicase has significantly reduced the need for hemodialysis consequent upon tumor lysis syndrome. Recent protocols incorporate a prophase of reduced intensity to decrease the risk of severe tumor lysis syndrome.[67] In the setting of abdominal BL, intestinal perforation, obstruction, or gastrointestinal bleeding may not occur until after the initiation of chemotherapy as the lymphoma begins to regress.

Localized resected mature B-cell NHL (including both BL and DLBCL) could be cured without significant toxicity by two courses

TABLE 88.6 Berlin-Frankfurt-Münster Risk Group Classification of Mature B-Cell Lymphomas

Risk Group	Resection Status	Stage and Initial Serum LDH Level
R1	Complete	
R2	Incomplete	Stage I+II Stage III and LDH <500 U/L
R3	Incomplete	Stage III and LDH ≥500 U/L but <1000 U/L Stage IV/B-AL and LDH <1000 U/L and CNS-negative
R4	Incomplete	Stage III and LDH ≥1000 U/L Stage IV/B-AL and LDH ≥1000 U/L and CNS-negative
R4 CNS+	Incomplete	Stage IV/B-AL and CNS-positive

of chemotherapy.[37,41–43,66,68] Advanced-stage BL requires aggressive combination chemotherapy with CNS prophylaxis (Table 88.7). Cyclophosphamide, methotrexate, and cytarabine at high doses have been used most recently, with or without anthracyclines and epipodophyllotoxins. Therapy should be started as quickly as possible upon presentation since this tumor grows very rapidly, and subsequent cycles should be administered in an intensive fashion as soon as recovery occurs from the last cycle. CNS prophylaxis is needed because without it approximately 30% to 50% of patients will relapse in the CNS,[69] while 6% to 11% develop CNS relapse if adequate prophylaxis is given.[33] CNS prophylaxis includes high-dose methotrexate and cytarabine to penetrate the CNS, together with intensive intrathecal chemotherapy. Risk-adapted therapy used in the French-American-British (FAB)/LMB-96 study and the NHL-BFM95 study conferred an excellent EFS in advanced-stage patients.[65–67] Treatment intensity was escalated based on tumor burden and response to therapy. Both regimens have significant hematologic toxicity. Therefore, both the FAB/LMB-96 study and the NHL-BFM 95 study successfully reduced therapy for low- and intermediate-risk patients without a compromise in survival. However, both studies failed to safely reduce the intensity of therapy for patients with advanced stages of disease.

Rituximab is a mouse/human chimeric monoclonal antibody against CD20 that is highly expressed in BL and DLBCL. In adults, the addition of Rituximab to CHOP chemotherapy is beneficial for DLBCL and has been given safely in combination with intensive BL therapy. In children, single-agent rituximab showed activity for BL in a phase II window study for newly diagnosed patients,[70] and the Children's Oncology Group showed the safety of adding rituximab to the LMB backbone for the treatment of BL.[71,72] Current clinical trials address the question of whether rituximab added to standard chemotherapy can improve the EFS of patients with advanced disease and showed superior outcome with rituximab.[47] The rituximab window prior to standard NHL-BFM chemo and additional doses in high-risk patients are currently under evaluation in the ongoing NHL-BFM and Nordic Society of Pediatric Haematology and Oncology (NOPHO) trial B-NHL 2013 along with the kinetics of immune reconstitution (NCT03206671). This trial enrolls low, standard, and high-risk patients.

Local radiation therapy has no role in BL because it is chemosensitive and often diffuse. CNS radiation has been used in the past for CNS involvement at diagnosis but did not show an impact on outcome in this group. Surgery is no longer routinely used for BL.

TABLE 88.7 **Outcomes for Burkitt Lymphoma and Diffuse Large B-Cell Lymphoma**

However, patients with localized disease resected at diagnosis are eligible for reduced chemotherapy, as noted previously.

Diffuse Large B-Cell Lymphoma

Introduction

DLBCL includes a heterogeneous group of neoplasms of transformed B cells, accounting for 10% to 13% of pediatric NHL.[14] DLBCL has some distinctive biologic and clinical features, described in more detail below.[73] DLBCL involving the mediastinum need to be distinguished from the primary mediastinal large B-cell lymphoma (PMBCL) that represents a distinct subtype of B-NHL in the WHO classification. In addition, the current version of the WHO classification introduced pediatric follicular lymphoma, marginal zone lymphoma, and grey zone lymphoma.

Epidemiology

The incidence of DLBCL increases with age, being more common in the second decade of life.[17,74] It is rare in children younger than 4 years of age. The gender difference is far less than in BL. PMBCL is more common in adolescents, with no gender difference.[14,73]

Pathobiology

Most pediatric DLBCL cases have a germinal center mature B-cell phenotype.[74] Nuclei are usually more than twice the size of normal lymphocytes. They express pan-B-cell antigens, including CD19, CD20, CD22, and CD79a with or without surface immunoglobulin. Most express CD10 and BCL6, and approximately 40% express BCL2. However, breaks or translocations in *BCL2* and *BCL6* are rare in pediatric DLBCL. Unlike adult DLBCL, pediatric cases rarely demonstrate the t(14;18) translocation.[73,74] Gene profiling has led to the subclassification of adult cases into germinal center B-cell like, activated B-cell like, and type 3 (not belonging to the first two groups) phenotypes. The great majority of children have the germinal center B-cell like phenotype.[74,75] Interestingly, this phenotype has a better prognosis in adults, and childhood DLBCL outcomes are better than adult outcomes. Morphologic variants of DLBCL include centroblastic, immunoblastic, anaplastic, and T-cell/histiocyte rich variants.[76] Although DLBCL is clearly heterogeneous, the clinical value of these distinctions is unclear in children.

PMBCL is thought to originate from medullary thymic B cells. B-lineage antigens and CD30 are often positive, but surface immunoglobulin and HLA class I and II molecules are absent or incompletely expressed.[73] *MYC*, *BCL2*, and *BCL6* genes are not rearranged. PMBCL is associated with gains in chromosome 9p (involving *JAK2*) and 2p (involving c-*rel*). They commonly demonstrate the inactivation of *SOCS1*.[77,78] Variable degrees of sclerosis occur in PMBCL,[79] as well as occasional lymphocytes, eosinophils, and Reed-Sternberg-like cells, sometimes leading to confusion with HL.

Clinical Manifestations

DLBCL is often more localized than BL and is less likely to involve the bone marrow or CNS.[33] Nodal disease is more common in DLBCL than in BL, but extranodal disease is frequent. Common sites of involvement include the head and neck, abdomen, mediastinum, and bone. PMBCL is locally invasive and frequently associated with SVC syndrome or airway compression. Pleural or pericardial effusions are present in approximately 40% of PMBCL cases,[79] and kidney metastases are frequent.[73]

Differential Diagnosis.

The differential diagnosis of DLBCL encompasses BL, pB-LBL, and nodular lymphocyte-predominant HL. BL is distinguished from DLBCL by morphology, although atypical BL shows more pleomorphism than typical BL. BCL2 negativity, high cell proliferation, and translocations involving c-*myc* may suggest BL but are not definitive. DLBCL with its mature phenotype differs from pB-LBL by a lack of TdT expression. DLBCL and nodular lymphocyte-predominant HL share some similar features and derive from a common B-cell clone. DLBCL may represent the clonal progression of nodular lymphocyte-predominant HL. PMBCL can also be confused with HL, and an adequate biopsy is essential for diagnosis. PMBCL and other DLBCL are distinguished clinically, as PBMCL typically resides within the thymic area while mediastinal DLBCL usually involves mediastinal lymph nodes.

Prognosis (Staging)

Murphy classification and the revised IPNHLSS are used to stage DLBCL.[16,80] There is no difference in outcomes between BL and DLBCL based on histology, and the treatment is identical in children and adolescents.[73] Outcomes for pediatric DLBCL are superior to adults, with 5-year overall survival (OS) of 90% for current therapies. Adolescent females fared worse than adolescent males with DLBCL on NHL-BFM protocols.[41] BCL2 expression is not an unfavorable prognostic factor in children with DLBCL, in contrast to adults with DLBCL.[74] Prognosis is poorer for children and adolescents with PMBCL (5-year EFS 65% to 75%).[55,79,81] In the setting of PMBCL, LDH of 500 U/l or more has a worse prognosis.[79] For adult patients with PMBCL, favorable outcome was reported using a dose-adjusted EPOCH-rituximab regimen with continuous infusions of etoposide, doxorubicin, vincristine, and bolus[66,67] administrations of cyclophosphamide and prednisone.[82] In a small pediatric series similar excellent results were observed but require systematic prospective validation.[83]

Therapy

In children and adolescents, all mature B-cell lymphomas are usually treated similarly with good results. Despite biologic and clinical differences, BL therapy is effective in DLBCL (see Table 88.7).[73] Risk-adapted therapy with LMB (SFOP) or B-NHL (BFM) backbones consists of short, dose-intense courses of chemotherapy including steroids, vincristine, high-dose methotrexate, cyclophosphamide, doxorubicin, cytarabine, etoposide, and intrathecal chemotherapy.[64,73] As described for BL, risk-adapted therapy based on FAB/LMB-96 and NHL-BFM 95 are also the current standard of care for childhood DLBCL.[41,64,66,67] Rituximab added to standard chemo regimen improved the outcomes for patients with advanced disease.[10,47] The impact of rituximab for limited-stage B-NHL is currently being evaluated in the NHL-BFM and NOPHO trial B-NHL 2013 (NCT03206671).

Having evolved from BL regimens, DLBCL treatment has traditionally included intrathecal chemotherapy for CNS prophylaxis. Since the risk of CNS involvement is lower for DLBCL than for BL, it is unclear if CNS-directed therapy should be as intensive.[33,73] Local radiation has no role in front-line DLBCL therapy.[73] As mentioned, the optimal treatment strategy for PMBCL has not been established yet, but favorable results with DA- EPOCH-R were reported for a small series of the NHL-BFM group and in a retrospective analysis.[84] However, in the first prospective multisite international study evaluating children and adolescents with PMBCL ($n = 46$), DA-EPOCH-R did not improve the EFS compared with historical controls. (ClinicalTrials.gov identifier: NCT01516567).[85] Hence, further studies are required to determine the optimum therapy for children and adolescents with PMBCL including evaluating the impact of checkpoint inhibitors, which is currently the focus of prospective trials (NCT04759586).

Anaplastic Large Cell Lymphoma

Introduction and Epidemiology

Most childhood NHLs previously classified as large cell lymphomas fall into the category of ALCL in the REAL and WHO classification. This entity was first described in 1985 as a clinicopathologic variant of large cell lymphoma with a predilection for young patients.[86]

Pathobiology

ALCLs are characterized by the proliferation of large, pleomorphic cells with one or more prominent nucleoli. The cells preferentially involve lymph node sinuses and extranodal sites (notably skin, bone, and soft tissue) where they grow in a cohesive pattern. The cells express epithelial membrane antigen (EMA) and CD30 (Ki-1) antigen—a 120kd membrane-bound molecule a member of the tumor necrosis factor (TNF) receptor superfamily—previously found in association with Hodgkin disease. A soluble (88kd) form of the CD30 molecule is found in high levels in the serum of nearly all patients with ALCL.[87] Marked elevation of soluble CD30 levels in patients with ALCL correlates with a higher risk of relapse, and soluble CD30 levels correlate with clinical disease status, returning to normal with the attainment of complete remission and increasing with disease recurrence.

The ALCLs are associated with chromosomal rearrangements involving the long arm of chromosome 5 at position q35.[88] In most cases, this translocation includes material from chromosome 2p23 [t(2;5)(p23;q35)] resulting in the fusion of the NPM nucleolar phosphoprotein gene on chromosome 5q35 to anaplastic lymphoma kinase (ALK), a tyrosine kinase gene on chromosome 2p23. The hybrid protein produced from the translocation links the amino terminus of nucleophosmin (NPM) with the catalytic domain of ALK.[89] Deregulated expression of the truncated ALK may contribute to malignant transformation. The chimeric NPM-ALK protein is clearly oncogenic, perhaps through the triggering of antiapoptotic signals via phosphatidylinositol 3-kinase/Akt, although secondary molecular events may be required for lymphomagenesis.

Immunologic and molecular biologic studies reveal that most cases of Ki-1+ ALCLs are derived from activated T-cells, although non-T, non-B-cell (null-cell) cases and more rarely B-cell cases occur.[90] Based on extended testing for T-cell antigens and examination of the configuration of TCR genes, many "null" cell cases are, in fact, T-lineage neoplasms, although a minority may be derived from NK cells.[91] The diagnosis of ALCL can be difficult, and many cases are initially misdiagnosed as Hodgkin disease. Molecular techniques (reverse transcriptase-polymerase chain reaction [RT-PCR]) to detect the fusion gene produced of the t(2;5) in many cases of ALCL confirms the diagnosis. Variant translocations where *ALK* is involved with other partner genes on other chromosomes limit the application of RT-PCR for diagnosis. However, the t(2;5) results in the expression of the NPM-ALK fusion protein, while the variant translocations result in the up-regulation of *ALK*. The ALK1 monoclonal antibody recognizing the formalin resistant epitope of both the NPM-ALK chimeric protein and normal ALK thus serves as a useful diagnostic reagent for identifying cases of ALCL. It should be noted that the distribution of ALK staining varies depending on the translocation. Further, ALK expression is a feature of inflammatory myofibroblastic tumors (IMT); however, confusion with ALCL can be minimized by testing for other hematopoietic markers, and the distinction is not usually difficult for experienced pathologists.

Clinical Manifestations

ALCL is rare, accounting for 8% to 13% of childhood NHLs and approximately 30% to 40% of the pediatric large cell lymphomas. Approximately one-third of the cases present with localized disease, while the majority have advanced disease at presentation, although bone marrow and CNS involvement is uncommon.[92] A rare leukemic presentation of ALCL possibly associated with the small cell variant of ALCL has been described. Systemic symptoms (fevers, weight loss) are frequently present in advanced-stage disease. Cutaneous (spontaneously regressing) lesions sometimes accompany disease at other sites, but skin involvement is not universal.[86] A variety of presenting sites—both nodal and extranodal—can occur, including the mediastinum, gastrointestinal tract, and bone. Further, tumors may invade adjacent structures and be associated with ascites and other intraabdominal sites of disease, including kidney, liver, and lymph nodes. The outcome of children with ALCL in most series has been good (with survivals ranging from 70% to 85%), albeit inferior to that of children with Burkitt and diffuse large B-cell lymphomas (Table 88.8).

Diagnosis and Differential Diagnosis

Immunophenotyping and immunohistochemistry are critical for the definitive diagnosis of ALCL. The typically ALCL immunophenotype is: CD30$^+$, CD15$^-$, CD45$^+$, in contrast to HL which is typically CD30$^+$ and CD15$^+$. Over 60% of cases of ALCL express 1 or more T-cell antigens (CD3$^+$, CD43, or CD45RO), and ALK protein is detected in most cases (over 60%).

Prognosis (Staging)

The disease stage of ALCL is determined according to the staging system described by Murphy (see Table 88.2).[35] As for other types of childhood NHL, stages I and II are considered limited-stage disease, whereas stage III represents advanced-stage disease. Stage IV is reserved for children with bone marrow or CNS involvement. For

TABLE 88.8 **Outcomes for Anaplastic Large Cell Lymphoma**

Protocol	*n*	Stage	Regimen	EFS
POG 8314 and 8719[98]	72	I–II (resected)	CHOP ± maintenance	88% (5-year)[a]
CCG 5941[95]	86	Non-localized	Multi-agent, + maintenance	68% (5-year)
NHL-BFM 90[99]	9	I–II (resected)	Multi-agent, risk-adapted (short-pulse B-NHL type therapy)	100% (5-year)
	65	II (non-resected)–III		73% (5-year)
	14	IV and multifocal bone involvement		79% (5-year)
ALCL-99[94]	225	I–IV	Multi-agent, risk-adapted, 3–6 cycles chemotherapy	81% (3-year) (100% EFS in completed resected patients
COG ANHL0131[104]	125	III or IV	APO versus APV	74% (3-year) in APO group 79% (3-year) in APV group
COG ANHL12P1[108]	68	II–IV	ALCL-99 plus brentuximab vedotin	79% (2-year) overall 100% stage I 76.7% stage II 66.7% stage III

[a]ALCL and DLBCL combined.
ALCL, Anaplastic large cell lymphoma; *APO*, doxorubicin, prednisone, vincristine, methotrexate, 6-mercaptopurine; *APV*, doxorubicin, prednisone, vinblastine, methotrexate, 6-mercaptopurine; *BFM*, Berlin-Frankfurt-Münster; *CCG*, Children's Cancer Group; *CHOP*, cyclophosphamide, doxorubicin, vincristine, prednisone; *EFS*, event-free survival; *NHL*, non-Hodgkin lymphoma; *POG*, Pediatric Oncology Group.

elderly patients with cutaneous CD30$^+$ ALCL, the 5-year disease-free survival appears to be determined by the extent of limb involvement; however, this has not been shown in children, possibly due to the fact that primary cutaneous ALCL is rare in the pediatric population.[93]

For systemic ALCL, studies have suggested that the stage of disease may be more important than the expression of the ALK protein. The European Intergroup for Childhood Non-Hodgkin Lymphoma defined three factors (mediastinal involvement, visceral involvement, and skin lesions) associated with poorer prognosis in childhood ALCL.[94] This group conducted a multivariate analysis (merging preexisting databases from BFM, SFOP, and United Kingdom Children's Cancer Study Group studies) and identified poor prognosis (1 or more risk factors) and standard risk groups with 5-year PFS of 61% and 89%, respectively. However, it is important to note that this study was not done as a prospective collaborative study. In contrast, the Children's Cancer Group Study 5941 reported that only bone marrow involvement significantly changed the 5-year survival rate.[95]

The presence of ALK autoantibodies appears to be associated with decreased clinical risk factors and lower clinical stage, resulting in a lower cumulative incidence of relapses.[96] There is no correlation between outcome and the ALK translocation type. However, recently the SFOP group has shown that for patients with ALK+ ALCL, the presence of a small cell or lymphohistiocytic component is associated with a worse prognosis.[97]

Therapy

The optimal treatment approach for patients with ALCL has yet to be determined, as evidenced by a wide range of successful treatment strategies. In the United States, children with advanced-stage CD30+ ALCL are generally treated with non-ALCL large cell lymphoma regimens, with long-term EFS rates ranging from 60% to 75% (see Table 88.8).[94,95,98,99] In a randomized trial performed by the pediatric oncology group (POG), the addition of intermediate-dose methotrexate and high-dose cytarabine did not improve upon the 70% 4-year EFS achieved with APO alone.[100] The BFM reported 3-year EFSs of ~80% using a BL-based strategy.[99] Regimens designed specifically for children with CD30+ ALCL have been developed by the French (SFOP) and German Groups.[101] The SFOP also reported the successful salvage of ALCL patients with the weekly administration of single-agent vinblastine.[102]

The impact of incorporating vinblastine into two different frontline treatments for ALCL (the BFM B-cell approach [multi-national European trial]) and APO (Children's Oncology Group [COG] trial in the United States) was then studied in a randomized fashion. In the European study, patients receiving the vinblastine plus chemotherapy regimen had a better EFS in the first year after therapy (91%) than those not receiving vinblastine (74%); however, at 2 years of follow-up, EFS was 73% for both groups.[103] Similarly, The COG ANHL0131 study evaluated whether a maintenance regimen including vinblastine compared to APO (doxorubicin, prednisone, vincristine, methotrexate, 6-mercaptopurine) alone would result in superior EFS. Post induction patients were randomized to receive APO with vincristine every 3 weeks or a regimen that substituted vincristine with weekly vinblastine (APV). In this study of 125 patients, no difference was observed between the patients randomized to the APO versus APV arms in either EFS (3-year EFS 74% vs. 79% $P = .68$) or OS 84% vs. 86%, $P = .87$).[104]

In addition, the European study also showed that infusing methotrexate 1 g/m^2 over 24 hours was comparable to 3 g/m^2 over 3-hour infusions without intrathecal methotrexate.[105] However, 3 g/m^2 of methotrexate had less toxicity. Other studies have come to no firm conclusions. For example, (1) the POG-9317 trial demonstrated no benefit of adding methotrexate and high-dose cytarabine to 52 weeks of their APO (doxorubicin, prednisone, and vincristine) regimen,[100] and (2) the CCG-5941 study evaluated a more intensive induction and consolidation with maintenance for 1-year total duration of therapy again and had similar outcomes but with significant hematologic toxicity.[95]

Targeted therapy options are important areas of investigation for future studies since crizotinib, an ALK inhibitor, has had outstanding results in pediatric phase I studies in children with ALCL showing a nearly 100% response rate and minimal toxicity.[106] In addition, with the remarkable activity of brentuximab vedotin (tubulin-inhibitor conjugated monoclonal anti-CD30) in ALCL,[107] this led the COG to pursue testing the efficacy and toxicity of adding these two biologic targeted agents with standard ALCL-99 chemotherapy in newly diagnosed pediatric ALCL patients (ANHL12P1). In this study, 68 children with ALK+ ALCL were enrolled and received brentuximab vedotin (from 2013 to 2017) on day 1 of each of the chemotherapy 6 cycles. The addition of brentuximab vedotin to standard chemotherapy did not add significant toxicity, and with 14 relapses, the 2-year EFS was 79.1% (95% confidence interval [CI], 67.2 to 87.1) with a 2-year OS of 97.0% (95% CI, 88.1 to 99.2) that compared favorably to results obtained using conventional chemotherapy.[108] The results of the crizotinib arm have not been published yet (NCT01979536).

Relapsed Non-Hodgkin Lymphoma-Management

There is no standard treatment for relapsed NHL. Treatment usually consists of intensive chemotherapy to induce a complete or partial response, followed by autologous or allogeneic stem cell transplant.[49] Recent studies suggest that allogeneic transplant may be more effective than autologous transplant for relapsed NHL, particularly for LBL.[109] Outcomes are appreciably better for patients with a complete remission prior to transplant. Radiation may be useful prior to transplant in selected patients with an incomplete response to chemotherapy. However, with the increased area of study comparing commercial CD19 chimeric antigen receptor (CAR) T-cell therapy versus standard of care (including autologous stem cell transplant) in the adult NHL setting (NCT03391466 and NCT03570892), the utility of this therapy in the relapsed setting for pediatric patients is being actively evaluated. Pediatric and adolescent patients with relapsed/refractory B-NHL (including BL) were infused with tisagenlecleucel in the Novartis sponsored BIANCA trial demonstrating the feasibility and manageable safety in this population with aggressive disease (NCT03610724).

While the efficacy data of CD19-CAR-T therapy for pediatric B-NHL still needs to be determined, many other targeted immunotherapeutic modalities are being developed for relapsed/refractory B-NHL in adults, but few are being tested in pediatric patients. However, a pediatric phase II trial combining obinutuzumab with ifosfamide/carboplatin/etoposide (ICE) is ongoing (NCT02393157). The CD19/CD3 bispecific antibody Blinatumomab is active in adults and children with relapsed/refractory ALL and was also active in a small trial in adults with heavily pretreated relapsed/refractory DLBCL but is yet to be comprehensively evaluated in the pediatric setting.[110]

Outside of immune-based therapies, outcomes of relapsed disease typically vary by histologic subtype. Relapsed BL and DLBCL are often chemoresistant, and survival is only 10% to 20%. The COG used rituximab, ifosfamide, carboplatin, and etoposide (R-ICE) for salvage therapy in this population, achieving a 60% response rate (complete and partial).[111] Patients who achieve a complete remission should proceed to stem cell transplant.

Relapsed LBL is also frequently chemoresistant, and reported survival is 10% to 40%.[112–114] Salvage regimens used for ALL may be employed for LBL, and Nelarabine has demonstrated a 40% response rate in this setting for T-ALL and T-LBL in a phase II COG study.[115] Encouragingly, novel immunotherapeutic agents such as CD5-directed CAR-T cells (NCT03081910) are also being evaluated in pediatric patients with relapsed/refractory T-LBL.

Survival for relapsed ALCL is better than for other NHLs, reaching 40% to 60%.[6,112,116] Vinblastine monotherapy as salvage therapy resulted in a complete remission rate of 83% in one study.[117] Brentuximab vedotin, an antibody against CD30, has been used successfully in adults and in pediatrics with relapsed ALCL.[118,119] Crizotinib, an ALK inhibitor, has also shown promise in adults in early clinical trials for relapsed ALCL patients and has shown remarkable results in phase I studies in children.[106] Autologous transplant has been used successfully for some patients, but allogeneic transplant may have better outcomes and is preferred for patients with bone marrow or CNS involvement, early relapse, and /or CD3-positive relapsed ALCL.[41,109,120,121]

Post-Transplant Lymphoproliferative Disorder

Post-transplant lymphoproliferative disease (PTLD) is discussed in other Chapters. Therefore, this section merely serves to summarize the issues specific to the pediatric population. The major pediatric populations where PTLD is most frequently seen are patients with congenital immune deficiencies or patients after bone marrow or solid organ transplant. Further, stem cell transplant recipients with underlying immunodeficiencies such as Wiskott-Aldrich syndrome (WAS) represent an independent risk group for EBV-associated lymphoproliferative disease (LPD).[122] Patients with primary, congenital immunodeficiencies such as X-linked agammaglobulinemia and AT have an incidence of EBV-associated LPD ranging from 0.7% to 15%.[123] The incidence of PTLD after solid organ transplant is higher in children than in the adult population. The disease is heterogeneous, but in children, it is most frequently of B-cell origin and EBV associated. In the United States, 150 new cases are diagnosed in children each year.

Numerous therapeutic approaches to PTLD have been explored in children, but there has been a paucity of multicenter collaborative studies for this disease. Withdrawal or reduction of immunosuppression is often considered as first-line therapy for PTLD but depends on whether the patient has a recovering immune system sufficient to eradicate EBV-infected B cells and depends on stage and disease histology. For the pediatric hematopoietic stem cell transplant (HSCT) patient, strategies have included reduction in immune suppression, rituximab,[124] donor lymphocyte infusions,[125] and EBV-specific T-cell directly therapy.[126] The advantages of T-cell-based therapies over antibody therapy is that EBV-specific T-cell immune reconstitution is restored, thus reducing the risk for disease recurrence. Responses to donor-derived EBV-specific T-cell therapies developed at multiple centers for pediatric patients range from 70% to 85%.[126,127] Immune-based therapies are generally preferred in this population since the use of chemotherapy in patients with LPD post HSCT is associated with high mortality rates secondary to increased infectious complications.[128] However, hydroxyurea and immune-based therapies may be an option for patients with CNS disease.[129] After solid organ transplant (SOT), modalities such as radiotherapy or surgical resection for localized LPD can result in complete remissions. One study evaluated the efficacy of low-dose cyclophosphamide and prednisone for pediatric patients with PTLD after SOT. All patients had failed reduction of immune suppression and received 6 cycles. The 2-year event-free and OS was 67% and 73%, respectively.[130] Subsequently, the COG was evaluated in a phase II study (ANHL0221) where the CD20 monoclonal antibody was added to the previously reported regimen of low-dose cyclophosphamide and prednisone regimen (http://clinicaltrials.gov/show/NCT00066469). All patients had refractory PTLD after SOT, CD20+, EBV+ PTLD in pediatric patients following solid organ transplantation. The study showed that the addition of the CD20 monoclonal antibody to the previously reported regimen of low-dose cyclophosphamide and prednisone demonstrated an EFS and OS of 71% and 83%, respectively.[131] Therefore, to build on the success of this first cooperative group trial for PTLD, the COG have just completed a feasibility and safety study (NCT02900976) administering "off the shelf" third-party allogeneic EBV/latent membrane protein (LMP)– cytotoxic T lymphocytes (CTLs)[132] to determine the safety and efficacy in patients with PTLD post SOT in combination with rituximab. This represented the first multicenter study of its kind combining antibody therapy with "off the shelf" antigen-specific T-cell therapy for this disease.

Finally, for patients refractory to these low-dose regimens or patients with definitive features of malignancy, standard lymphoma chemotherapy regimens are used depending on histological subtype (e.g., BL vs. DLBCL vs. HL directed therapy).

HODGKIN LYMPHOMA

Epidemiology

HL comprises 10% of all lymphomas and approximately 10% of pediatric cancers[2] and has a bimodal incidence, with one peak at 15 to 34 years of age, and a second peak in the 6th decade. In children, the highest peak is among 15 to 19-year-olds (29 per million per year) and is least frequent in children under 5 years. There is an age-dependent sex predominance, with a male predominance in children under 5 years (male:female ratio of 5.3:1) and a slight female predominance in children aged 15 to 19 years (male:female ratio of 0.8:1). HL (especially the nodular sclerosing subtype) is classically associated with higher socioeconomic status, increased incidence in single-family homes, smaller family sizes, and a higher level of maternal education. In contrast, mixed cellularity HL is inversely related to socioeconomic status. It is commonly postulated that delayed exposure to some environmental antigen may trigger the development of HL, and higher rates of certain childhood infections (e.g. varicella, measles, mumps, rubella) are negatively associated with HL development.[133]

HL has been shown to have a genetic predisposition, although this is incompletely understood. Siblings of HL patients have a 5-fold (50-fold for monozygotic twins) increased risk of developing HL.[134] There is also an increased risk among parent-child pairs, though not between spouses, supporting a genetic rather than a uniquely environmental predisposition. Genome wide association studies have identified HL susceptibility loci,[135] implicating dysfunction of the germinal center reaction, disruption of T-cell differentiation and function, and constitutive activation of nuclear factor kappa B (NFκB) as mechanistic factors associated with elevated risk for HL.

Environmental factors are nevertheless involved in HL.[136] Approximately 40% of all HL cases in economically developed countries harbor EBV in the Hodgkin and Reed–Sternberg (HRS) cells. EBV positivity of the malignant HRS populations is more common in children under 10 years of age and is highly associated with childhood HL with mixed cellularity subtype (80% of cases) characteristically seen in developing countries. The EBV protein latent membrane protein 1 (LMP1) may be the key in the oncogenic process since it can elicit B lymphocyte transformation *in vitro*.[137]

There is also a relationship between the development of HL and cell-mediated immune deficiency with an increased incidence in patients with HIV,[138] patients on chronic immunosuppressive therapy following solid organ transplantation, and common variable immunodeficiency (CVID). It remains unclear whether the underlying immune deficiency commonly seen in HL is primary, secondary, or both.[137]

Pathobiology

HL is considered to be slow growing with a tendency to spread to contiguous lymph nodes. Only in advanced stages is there evidence of blood vessel invasion and spread to more distant organs.[139] Over the past 30 years, significant advances have been made in the treatment of pediatric HL, such that over 85% of children are cured with chemotherapy and/or radiation even with stage III/IV disease.

HL is notable for the characteristic B-cell-derived HRS cells found in a background of an inflammatory microenvironment usually comprising Tregs, Th2 T cells, macrophages, and eosinophils. The REAL/WHO classification identifies two main subtypes: classical HL and lymphocyte-predominant HL. Classical HL accounts for most cases in adolescents and young adults and is characterized by HRS cells which are usually CD15+ and CD30+. HRS cells do not express B-cell markers such as CD19 and CD79A, although CD20 is expressed in 5% to 10% of cases. Mixed cellularity HL accounts for 1/3 of cases diagnosed in children less than 10 years. The histopathology shows frequent HRS cells on a background of normal reactive immune cells including T lymphocytes, plasma cells, eosinophils, macrophages, and histiocytes. Lymphocyte-predominant HL and lymphocyte-rich classical HL may both have nodular appearances, but the former is more commonly CD15 negative and usually has strong CD20 and CD45 positivity, thus distinguishing it from classical HL.[140]

Multiple prognostic markers related to HRS cells, the microenvironment or both, have been evaluated in patients with HL, although none have been found to be superior to current clinical or radiographic factors.[141] More recently, circulating tumor DNA analysis by next-generation sequencing has shown early promise for the diagnosis and disease monitoring after initiation of therapy, including studies in pediatric HL[142,143]

Clinical Manifestations

The majority of pediatric patients with HL present with painless, firm, "rubbery" lymphadenopathy, most commonly in the cervical/supraclavicular regions. Over 70% of adolescents and young adults present with mediastinal disease, which can be asymptomatic. This presentation is less frequent in younger children and may be related to a lower incidence of nodular sclerosis HL and a greater frequency of mixed cellularity or lymphocyte-predominant HL in this group. Approximately one-quarter of patients present with systemic "B" symptoms including fevers, weight loss, and drenching night sweats. The majority of pediatric patients presenting with HL have stage I–III disease (involvement of lymph nodes and/or the spleen only) with a minority (approximately 15%) presenting with stage IV disease (noncontiguous extranodal involvement such as bone marrow, lung, liver, and/or bone).

Staging

Pediatric HL is staged using the Ann Arbor staging system (with subsets A and B used for the absence or presence of B symptoms, respectively) (Table 88.9).[144] Briefly, stage I involves a single lymph node region. Stage II involves two or more lymph node regions on the same side of the diaphragm. Stage III involves lymph node regions above and below the diaphragm. For stages I–III, if there is an extension to an adjacent extralymphatic region/organ, then this is designated E (e.g., stage IIE). For stage III, if there is splenic involvement, this is designated stage IIIS. Finally, for stage IV disease, there is noncontiguous involvement of one or more extralymphatic organs or tissues +/− involvement of associated lymph nodes.

TABLE 88.9 **Ann Arbor Staging System for Hodgkin Lymphoma**

Stage I
Involvement of a single lymph node region (I) or of a single extralymphatic organ or site (I_E)
Stage II
Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site and one or more lymph node regions on the same side of the diaphragm (II_E)
Stage III
Involvement of lymph node regions on both sides of the diaphragm (III), which may be accompanied by involvement of the spleen (III_S) or by localized involvement of an extralymphatic organ or site (III_E) or both (III_{SE})
Stage IV
Diffuse or disseminated involvement of one or more extralymphatic organs or tissues with or without associated lymph node involvement

Note: The absence or presence of fever higher than 38°C for three consecutive days, drenching night sweats, or unexplained loss of 10% or more of body weight in the 6 months preceding admission are to be denoted in all cases by the suffix letters A or B, respectively. Suffix letter E denotes extralymphatic extension from contiguous nodal disease. Disease involving the spleen is designated a suffix letter S, and mediastinal bulk is often designated with an X.

Treatment

Despite the excellent outcomes for children with HL, there is still no ideal therapeutic approach. Consensus guidelines from the National Comprehensive Cancer Network (NCCN) provide specific pediatric HL treatment options based on risk status and disease staging using results from recent clinical trials.[145] Generally, combination chemotherapy with or without low-dose involved field radiation is used with varying intensities and duration depending usually on disease stage and prognostic factors such as disease bulk and B symptoms. However, studies of late effects in these patients[146] have fueled cooperative groups in particular to explore regimens with decreased radiation and/or chemotherapy doses, especially for children with low-risk disease. Implementation of risk-adapted treatment approaches for pediatric HL has resulted in a 20% reduction in risk for serious or fatal chronic health conditions.[147] Risk stratification for treatment assignment varies considerably between the pediatric HL research groups, thus limiting comparisons between trial results. The general consensus, however, is that chemotherapy should be given to all HL patients, with or without radiation. The exception to this approach is patients with single node stage I, completely resected, nodular lymphocyte-predominant HL, who can achieve cure with surgery alone.[148,149]

Chemotherapeutic agents used for the initial treatment of pediatric HL are similar to those used in adults and include alkylating agents, corticosteroids, vinca alkaloids, antimetabolites, doxorubicin, bleomycin, dacarbazine, and etoposide. However, doxorubicin (or Adriamycin) is associated with cardiac toxicity and bleomycin can lead to pulmonary fibrosis and alkylators may impair fertility. Therefore, many cooperative group studies have developed hybrid regimens using lower cumulative doses of alkylators, doxorubicin, and bleomycin, especially for low-risk (stages I–IIA; no bulk; no B symptoms) and intermediate-risk (all stage I and II patients not classified as early stage; and variably stage IIIA and stage IVA) disease. Results of clinical trials by the major international pediatric HL study groups are summarized in Table 88.10. Trials differ by the use of chemotherapy regimens of varying dose intensity, as well as the criteria for the omission of radiotherapy. The German Society of Pediatric Oncology and now in conjunction with other European pediatric oncology centers (Euronet consortium) has investigated OEPA (vincristine, etoposide, prednisone, doxorubicin) for low risk and OEPA with COPDac (cyclophosphamide, vincristine, prednisone, dacarbazine) for intermediate- and high-risk groups.[150] In North America, the COG has primarily evaluated ABVE-PC (doxorubicin, bleomycin, vincristine, etoposide, prednisone, cyclophosphamide) and its derivatives across the risk groups.[151,152]

Radiotherapy usage varies considerably. The COG reported that radiotherapy may be safely omitted in intermediate-risk patients who have a rapid reduction in tumor dimensions by CT after 2 cycles of chemotherapy, in the only published large randomized trial to evaluate omission of radiotherapy.[153] The European consortium has omitted radiotherapy for low-risk patients achieving a CR after 2 cycles of OEPA.[150] The utility of response by positron emission tomography (PET) is being evaluated in trials recently completed or in progress by all the major groups. In general, pediatric radiotherapy approaches utilize lower doses (15 to 25 Gy) and fields (involved field or node). The use of contemporary modalities such as Intensity-modulated radiotherapy, deep inspiration breath hold, and proton beam therapy, may further reduce long-term toxicities.

Therapies targeting CD30, a transmembrane glycoprotein that is present on Reed-Sternberg cells but is not expressed in most normal tissue, have been an area of significant interest as a means of

TABLE 88.10 Treatment Outcomes for Pediatric Hodgkin Lymphoma Clinical Trials

Study	*N*	Risk Group	Rx	Radiation (Gy)	EFS or DFS; OS (yr)

improving efficacy and replacing agents with long-term toxicities. Brentuximab vedotin (Bv) is an antibody-drug conjugate composed of a monoclonal anti-CD30 antibody linked to the anti-mitotic agent monomethyl auristatin E (MMAE). In a phase II study evaluating Bv in relapsed HL, the ORR was 75% with complete remission in 34%.[154] Replacement of vincristine with Bv in the OEPA/COPDac regimen was investigated in a phase 2 trial of 77 pediatric patients with high-risk HL by the Stanford, St. Jude, Dana-Farber Cancer Institute Consortium.[153] Approximately 1/3 of patients avoided radiotherapy based on attaining complete metabolic and anatomic response after two cycles, and high EFS and OS rates were observed at 3 years. A randomized phase 3 trial by the COG investigating the replacement of vincristine with Bv in the ABVE-PC has completed accrual with results anticipated soon (NCT02166463).

Management of Relapsed Hodgkin Lymphoma

For patients who relapse, response depends on whether or not they had favorable disease at diagnosis as well as the extent of disease at the time of relapse. Time to relapse and response to re-induction therapy are strong predictors of outcome.[155] The EuroNet Pediatric Hodgkin Lymphoma group has issued evidence and consensus-based guidelines for the management of relapse/refractory HL.[156] Low-risk patients can generally be salvaged with chemotherapy and involved-site radiation therapy and even without hematopoietic stem cell transplant results are very acceptable.

For all other patients, treatment of refractory, progressive, or relapsed disease includes induction chemotherapy with multiple chemotherapeutic agents, not generally used in the initial therapy (e.g., gemcitabine, vinorelbine, carboplatin/cisplatin, ifosfamide, and more recently brentuximab vedotin, alone or in combination with gemcitabine or bendamustine), followed by high-dose chemotherapy and autologous stem cell rescue. Conditioning regimens are generally alkylator based,[155] and the frequently reported regimens are CBV (cyclophosphamide [CY], carmustine, and etoposide) and BEAM (carmustine, etoposide, cytosine arabinoside, and melphalan).[155] None of these conditioning regimens produce a superior outcome in pediatric patients. The role of local radiation therapy either before or after HSCT is still unclear, although TBI is now generally not used.[156] Overall outcomes following HSCT have been estimated using a prognostic model for PFS derived from retrospective analyses of 606 pediatric and young adult patients undergoing HSCT using data from the CIBMTR from 1995 to 2010.[157] By stratifying patients into low-, intermediate- and high-risk groups, 5-year PFS probabilities are predicted as 72% (95% CI: 64 to 80), 53% (95% CI: 47

to 59), and 23% (95% CI: 9 to 36), respectively. Post HSCT Bv maintenance therapy has led to an approximate 30% reduction in PFS events among adults with no pre-HSCT use of Bv and high-risk factors for subsequent relapse.[158] Two-thirds of patients experienced peripheral neuropathy, although 90% showed improvement (including 73% with resolution) by 5 years. Pediatric data on this strategy for pediatric are lacking.

The role of allogeneic HSCT has also been investigated for patients with relapsed/refractory HL, although never in a prospective, randomized manner.[159] The use of submyeloablative regimens (generally fludarabine based) may reduce transplant-related mortality rates while still achieving a graft-versus lymphoma (GVL) effect in lymphoma patients receiving allografts and warrants further investigation in the pediatric population.[160,161]

Among the more promising approaches to activating therapeutic antitumor immunity in HL is the blockade of the immune checkpoint, programmed cell death protein 1 (PD-1) pathway. Classical HL is characterized by HRS cells surrounded by an extensive but ineffective inflammatory cell infiltrate. Increased PD-1 expression by T-lymphocytes in the microenvironment and increased PD-1 ligand expression by HRS cells allow evasion of T-cell-mediated destruction of HRS cells. Blocking the interaction between PD-1 and its ligands through the administration of PD-1 blocking antibodies can result in T-cell activation and a more florid tissue inflammatory response.[162] Nivolumab is associated with a high objective response rate of 87% among heavily pretreated patients with HL.[163] Another anti–PD-1 drug, pembrolizumab, was associated with a 60% response rate in a similar cohort of pediatric HL patients.[164] Studies are now investigating these agents in conjunction with other targeted therapies, including brentuximab vedotin. Preliminary results of a pediatric study of Bv with nivolumab, followed by Bv with bendamustine for those with an inadequate response have been reported in abstract format.[165] Overall, the complete metabolic response (CMR) rate was 86%, including 64% achieving a CMR after Bv with nivolumab alone.

Early investigations of CAR-T cells have been associated with durable responses and low toxicity among heavily pretreated patients.[166] Autologous cytotoxic, *ex-vivo* expanded T cells targeting EBV or other tumor-associated antigens are being explored for pediatric HL patients associated with EBV either as adjuvant therapy after transplant or for relapsed disease.[132,167]

In summary, most children with HL are initially treated with risk-adapted chemotherapy alone or in combination with low-dose involved site or node radiotherapy involving carefully designed radiation fields to achieve local disease control while minimizing bystander organ toxicity. Especially for low-risk patients, some studies suggest that the OS for patients receiving chemotherapy alone may be similar to that for patients receiving chemotherapy plus radiotherapy, despite possible differences in EFS. This is due to the fact that it is usually possible to salvage relapse after initial therapy.[168] If salvage therapy for such patients can be targeted and relatively nontoxic (e.g., using novel agents such as brentuximab),[169] then using a less intense initial regimen may be appropriate. Currently, however, salvage therapy for the majority of patients is typically more toxic and can lead to an unacceptable incidence of late events such as cardiac toxicities and secondary malignancies.[147,170] Therefore, strategies using a less intense upfront regimen should only be investigated within the context of a clinical trial. Future clinical studies therefore attempt to address this important issue by evaluating the prognostic significance of achieving PET negative disease after 2 cycles of chemotherapy and the use of upfront Bv and the checkpoint inhibitors, nivolumab, and pembrolizumab to replace more toxic modalities such as bleomycin and radiation therapy.[171]

RARE SUBTYPES OF LYMPHOMA

Other subtypes, which are observed rarely in children, deserve mention, but the rarity of these neoplasms in children makes generalizations and therapeutic recommendations difficult. Follicular lymphomas (characterized by the arrangement of malignant cells in aggregates separated by normal cells) that account for approximately 30 percent of adult NHLs are extremely rare in children. Children with follicular lymphomas tend to present with cervical lymph node involvement, (although primary tumors of the testis have been reported)[170] with early-stage disease, and have an excellent prognosis.[172,173] Unlike most cases of follicular lymphoma in adults where aberrant expression of bcl-2 (usually as a result of the t(14;18) translocation) is thought to play an important role in lymphomagenesis, the majority of cases of follicular lymphomas in children demonstrate neither the t(14;18) nor bcl-2 expression. Bcl-2 expression appears to occur more frequently in older children and is associated with advanced-stage disease at presentation and a more aggressive clinical course.[170–172]

Marginal Zone B-cell lymphomas arising in mucosa-associated lymphoid tissue (MALT) can arise in extranodal sites. They tend to present with localized disease and infrequently disseminate. Natural Killer Cell Lymphoma and NK-like T-cell lymphomas usually involve the upper aerodigestive tract (midline lethal granuloma, angiocentric T-cell lymphoma) but can present in the skin as well.[174–176] They are rare in children and follow a very aggressive clinical course, are often fatal, but may respond to high-dose chemotherapy with stem cell transplantation.[176] Peripheral T-cell lymphomas include a variety of neoplasms that have not yet been further specified. These lymphomas are rare in children, but advanced stage at presentation, often in association with systemic symptoms and hemophagocytic syndrome, is common, and an aggressive course is the rule.

FUTURE DIRECTIONS

Although there have been dramatic improvements in the treatment of children with NHL and HL over the past 25 years, approximately 25% of children with these tumors still relapse or fail to respond to initial therapy. Additionally, late effects such as anthracycline-related cardiomyopathy, secondary malignancies such as epipodophyllotoxin-related acute myeloid leukemia, and endocrine abnormalities such as cyclophosphamide-related azoospermia remain a concern.[170,177] Thus, a major task is to develop treatment strategies that provide a cure for the remaining 25% while reducing treatment-related morbidity. Several approaches appear promising.

The identification of both clinical and biologic features at the time of diagnosis that predict treatment failure will enable investigators to refine existing risk-adapted therapeutic approaches. Strategies to be considered for children at elevated risk for treatment failure include the intensification of existing regimens and the incorporation of new active or novel agents. More intensive therapy may require either autologous or allogeneic hematopoietic stem cell support. The administration of colony-stimulating factors may be necessary in some cases, although their role in therapy remains controversial. Novel approaches include the incorporation of immunotherapeutic agents into multi-agent chemotherapy regimens. For example, there is increasing experience with the anti-CD20 antibody (Rituximab) in pediatric patients with B-cell lymphomas.[70] A radiolabeled form of this product (Yttrium-90 Zevalin) has also yielded promising preliminary results in children.[178] CD30+ lymphomas such as ALCL, mediastinal B-large cell, and HL are also candidates for CD30 antibody therapy. Novel T-cell therapy approaches including CAR-T-cell therapies targeting CD19, CD5, and CD30 are being evaluated in phase I clinical trials in the pediatric setting. Moreover, antigen-specific T cells, especially T cells targeting EBV antigens have shown early evidence of efficacy in the prevention and treatment of EBV-related PTLD, NHL and HL.[126,132] Checkpoint inhibitors have high response rates in patients with HL.[164] Agents targeting specific molecular lesions (e.g., the ALK inhibitor for ALCL) are promising in children, and the implementation of anti-idiotype and anti-sense strategies are also being studied.

The continued investigation of molecular abnormalities and pathogenic mechanisms of malignant transformation associated with childhood lymphomas is essential. Micro-chip gene arrays have already identified clinically relevant subtypes of large B-cell lymphomas in adults.[179] Gene array analyses of BL, ALCL, and T-lymphoblastic disease have also been reported.[180] Similar studies are ongoing for childhood lymphomas, and preliminary results for T-lymphoblastic leukemia/lymphoma have been published.[181] Flow-sorting tissue for HRS and intratumor T cells and optimizing low-input exome sequencing is beginning to overcome the limitations of genomic evaluation in HL.[182] Comprehensive molecular characterization of childhood lymphomas may help to further refine disease classification, provide a means of detecting minimal residual disease (mrd) during clinical remission and enhance our assessment of early response.[183] Monitoring is facilitated by the finding that the level of mrd in the peripheral blood is comparable to that in the bone marrow in children presenting with advanced-stage lymphomas. Additionally, a more complete understanding of the molecular pathogenesis of pediatric HL and NHLs, will provide clues to new and better treatments directed toward tumor-specific molecular lesions.

CHAPTER 89

T-CELL LYMPHOMAS

Alessandro Broccoli and Pier Luigi Zinzani

T-cell lymphomas are a highly heterogeneous group of diseases sharing common origin from mature T-lymphocytes. Heterogeneity is appreciated on biologic and clinical grounds, both in terms of presentation (leukemic, nodal, extranodal, and cutaneous forms) and clinical behavior (aggressive *versus* indolent). Historically, peripheral T-cell lymphomas (PTCL) have always been separated by cutaneous T-cell lymphomas (CTCL), mostly because the former has a nodal and aggressive presentation, while the latter display relatively indolent (although progressive in most of the times) course.

Treatment approaches are mostly inadequate for the treatment of highly aggressive disease subtypes. New molecules hitting specific biologic targets have emerged as opportunities in patients with relapsed disease, yet with very short response durations. On the other hand, combinations of newer agents with conventional chemotherapy in untreated patients or strategies within chemo-free combination is an active field of research.

All the most frequent and clinically relevant leukemic T-cell lymphomas, PTCL, and CTCL will be treated in detail in the following sections of this chapter, with a focus on their epidemiology, morphology, biopathology, clinical manifestations, and prognosis. Current treatment approaches and future directions in the treatment of these diseases are discussed separately for leukemic T-cell lymphomas, PTCL, and CTCL at the end of the corresponding sections of the chapter.

ADVANCES IN MATURE T-CELL LYMPHOMA CLASSIFICATION

The significant advances occurred in the classification of both nodal and extranodal T-cell and natural killer-cell neoplasms have led to revisions: many of these changes are the result of genomic studies using approaches to examine the gene expression profile and the genetic landscape of these neoplasms. This box highlights the innovations with greater impact on clinical and therapeutic grounds. More details are found in the text.

- Peripheral T-cell lymphoma, not otherwise specified (PTCL-NOS). Subsets are recognized based on phenotype and molecular abnormalities as that may have clinical implications. Stratification however is mostly not a part of routine practice at present.
- Nodal T-cell lymphomas with T_{FH}phenotype. This is an umbrella category that encompasses the spectrum of nodal lymphomas with a T_{FH} phenotype. It includes AITL, follicular T-cell lymphoma, and other nodal PTCL with a T_{FH} phenotype and it serves to highlight the specific clinical and pathologic differences among these subtypes. Overlapping recurrent molecular and cytogenetic abnormalities are shared by these entities.
- Anaplastic large-cell lymphoma (ALCL), ALK^-. It is now a regarded as a definite entity that includes cytogenetic subsets with possible prognostic implications (e.g., rearrangements at *IRF4/DUSP22* locus).
- Breast implant–associated anaplastic large cell lymphoma (BIA-ALCL). New provisional entity distinguished from other ALK-ALCL; noninvasive disease associated with excellent outcome.
- Enteropathy-associated T-cell lymphoma (EATL). This denomination is only to be used for cases formerly known as type I EATL. It is typically associated with celiac disease.
- Monomorphic epitheliotropic intestinal T-cell lymphoma (MEITL). Formerly type II EATL, it is segregated from type I EATL and it is given a new definition due to its distinctive nature and lack of association with celiac disease.
- Lymphomatoid papulosis. New subtypes are described with similar clinical behavior but atypical histologic/immunophenotypic features.

CLASSIFICATION AND CELL OF ORIGIN

In 2017, the classification of hematologic and lymphoid neoplasm was updated, and the World Health Organization (WHO) now recognizes 29 established and provisional entities of mature T-cell non-Hodgkin lymphomas (Table 89.1). Provisional entities are lymphoma categories for which scientific data are not fully validated by large studies, thus forthcoming additional biologic elements are required to confirm—or not—these entities as established varieties.

This complex classification underscores the complexity and the great heterogeneity of these neoplasms, as it emerges from the advances in the molecular partitioning of these diseases. On the other hand, a more appropriate classification—based on morphological, immunophenotypical, clinical, and molecular grounds—is aimed at better stratifying patients in terms of prognosis and outcomes, at guiding physicians' decisions before and throughout treatment, and at providing new insights into potentially more effective therapies or drug combinations (see box on Advances in Mature T-Cell Lymphoma Classification).[1,2]

T-cell lymphomas are mature T-cell neoplasms, given that the postulated cell of origin is always a mature, post-thymic T-lymphocyte; this means that all mature T-cell lymphomas originate from a T cell born in the bone marrow that has already undergone T-cell receptor (TCR) gene rearrangement and has completed its pre-antigenic maturation (Fig. 89.1).[2] Mature T cells consist of α/β TCR (more than 90%) and γ/δ TCR lymphocytes: the former derive from precursor T cells that colonize the thymus, whereas the latter may originate from thymic or extrathymic tissues. The final maturation step of T-lymphocytes into either $CD4^+$ or $CD8^+$ T cells is determined by the kinetics and strength of TCR signals and the specific *milieu* of cytokines that dictates the selective expression of transcription factors.

Under the heading *mature T-cell lymphomas*, four broad groups of diseases can be distinguished according to their presentation (Table 89.2): leukemic, nodal, extranodal, and cutaneous. This partition has limitations, however, as in many instances nodal diseases may display a concomitant extranodal involvement, a cutaneous presentation, or a peripheral blood leukemic dissemination.[1]

Nodal Forms: Among the nodal forms, peripheral T-cell lymphoma, not otherwise specified (PTCL-NOS), angioimmunoblastic T-cell lymphoma (AITL), and anaplastic large-cell lymphoma (ALCL) and its two variants (distinguished according to the expression of the anaplastic lymphoma kinase [ALK]) are the most relevant entities. PTCL-NOS includes a heterogeneous group of neoplasms derived either from mature $CD4^+$ or $CD8^+$ α/β TCR lymphocytes and does not fit into any of the specifically defined entities. AITL originates from T follicular helper (T_{FH}) cells, a subset of T-lymphocytes that derive from naïve T cells homing to the germinal center of the lymph node and differentiating under the pressure of a strong TCR signal through the interaction with dendritic cells, cytokines, and B-lymphocytes. T_{FH} cells are putatively the normal counterpart of follicular T-cell lymphoma and PTCL with T_{FH} phenotype. ALCL-ALK$^+$ has been suggested to derive from thymocytes, whereas the origin of ALCL-ALK$^-$ is still debated.[1]

Extranodal Forms: Among the extranodal forms, NK/T-cell lymphoma nasal type (ENKL), subcutaneous panniculitis-like T-cell lymphoma (SPLTCL), hepatosplenic T-cell lymphoma (HSTCL), and primary intestinal T-cell lymphomas—which in turn are distinguished into enteropathy-associated T-cell lymphoma (EATL) and monomorphic epitheliotropic intestinal T-cell lymphoma (MEITL)—are the most clinically relevant subtypes. All nodal PTCL and most extranodal PTCL display an aggressive behavior, as they usually present with systemic symptoms and may cause a rapid clinical decay if not promptly treated. ENKL derives from the transformation of NK cells or cytotoxic innate cells, probably under the oncogenic pressure of the Epstein-Barr virus (EBV). HSTCL, EATL, and MEITL may derive from either innate cells (NK/T cells or γ/δ TCR CD3$^+$ lymphocytes), adaptive cells (CD4$^+$ or CD8$^+$ α/β TCR lymphocytes), or γ/δ TCR CD3$^+$ intestinal intraepithelial lymphocytes.[1,2]

Cutaneous Forms: Mycosis fungoides (MF) and primary cutaneous CD30$^+$ T-cell lymphoproliferative disorders are cutaneous diseases with a prolonged natural history and treatment may be unnecessary in the first stages of the disease. MF, however, invariably and progressively evolves into more aggressive stages, requiring an adequate treatment, and it is ultimately fatal. Sézary syndrome (SS) can be considered as the leukemic phase of MF, since the tumor arises in an extranodal organ—i.e., the skin—but also displays a characteristic leukemic picture: this is an aggressive form of CTCL, requiring specific treatment and characterized by a dismal prognosis. MF, SS, and CD30$^+$ T-cell lymphoproliferative disorders derive from CD4$^+$ T-lymphocytes with a specific tropism for the skin.

Leukemic Forms: These are mainly represented by T-cell prolymphocytic leukemia (T-PLL), T-cell large granular lymphocytic leukemia (T-LGL), aggressive natural killer (NK)-cell leukemia, and adult T-cell leukemia/lymphoma (ATLL). These diseases always arise in the bone marrow and then evolve with a peripheral blood leukemic presentation. T-PLL is discussed in more detail in this chapter.

CHRONIC T-CELL LEUKEMIAS

T-Cell Prolymphocytic Leukemia

T-PLL is a rare, post-thymic, mature T-cell neoplasm, accounting for 2% of mature lymphoid leukemias. It generally displays an aggressive clinical course and only a minority of patients are asymptomatic at presentation. Disease progression occurs rapidly, even in asymptomatic patients. Older adults are generally affected (median age of 61 years), with a male predominance.

Morphology and Pathobiology

Prolymphocytes are medium-sized cells, displaying a high nuclear-cytoplasmic ratio, with round, oval, irregular, or convoluted nuclei and a single prominent nucleolus. Their cytoplasm is agranular, frequently with blebs. In up to 20% of cases, prolymphocytes may resemble small lymphocytes or show a cerebriform nuclear appearance (Fig. 89.2). Bone marrow is constantly infiltrated, with a diffuse and interstitial pattern, as well as the spleen, which shows an expansion of both red and white pulp.

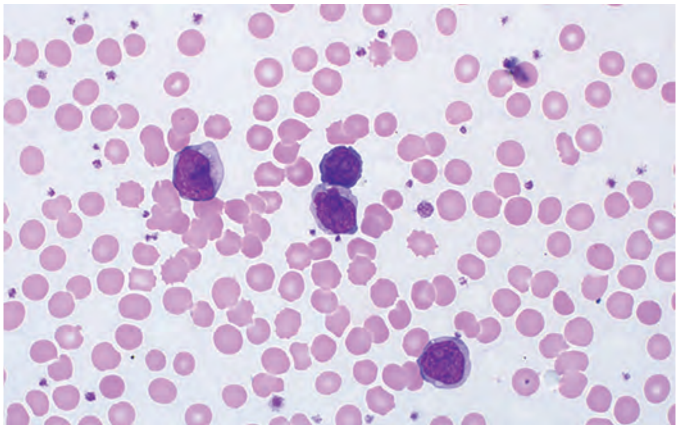

Figure 89.2 T-CELL PROLYMPHOCYTIC LEUKEMIA, PERIPHERAL BLOOD SMEAR. Prolymphocytes show a convoluted nucleus with an evident nucleolus and an irregular cytoplasmic contour.

In virtually all cases, the Xq28 (*MTCP1* locus) or 14q32.1 (*TCL1* and *TCL1b* loci) regions are involved in translocations or inversions with *TCRA/D* at 14q11: this determines the activation of all the three genes and their consequent overexpression, all being implied in T-PLL leukemogenesis by conferring resistance to cell death and determining cell growth arrest. Other complex karyotype alterations may be detected, above all chromosome 8 unbalanced rearrangements, like trisomy, monosomy, t(8;8)(p12;q11), or other translocations with another chromosomal partner. Mutations of the *ATM* gene at 11q21–q23 are also demonstrated in virtually all sporadic cases of T-PLL, reinforcing the association of T-PLL with ataxia-telangiectasia, regarded as a predisposing condition.

Clinical Manifestations

Splenomegaly, seen in almost two thirds of patients, and marked peripheral blood lymphocytosis (usually much higher than 100,000/mmc), with circulating prolymphocytes, are distinctive clinical aspects. Hepatomegaly and lymphadenopathies are seen in up to half of patients, as well as skin nodules, maculopapular rash, or erythroderma. Peripheral edema (periorbital or conjunctival), pleuroperitoneal effusions, or central nervous system involvement may also be present, especially during disease progression. Anemia and thrombocytopenia are usually documented, along with lactate dehydrogenase (LDH) elevation.

Diagnosis

It is established on both morphological and immunophenotyping tests. Tissue histology, however, is not mandatory for diagnosis. Immunophenotyping by flow cytometry demonstrates a positivity for CD7 (strong), CD5, and CD2, with lack of expression of terminal deoxynucleotidyl transferase (TdT) and CD1a. Most cases are CD4^{+} and CD8^{-} (60%), but the phenotype may also be CD4^{+}/CD8^{+} (15% to 25% of the cases) or CD4^{-}/CD8^{+} (10% to 15% of the cases). CD52 is expressed at high density. TCR α/β genes are rearranged in most of the cases, and just in a minority of instances a γ/δ rearrangement is detected.[3]

Table 89.3 displays the requirements to establish the diagnosis of T-PLL: the diagnosis is confirmed when all the three major criteria are met or if the first two major criteria and one minor criterion are met.

TABLE 89.3 **Criteria to Establish the Diagnosis of T-Cell Prolymphocytic Leukemia**

Major Criteria	Minor Criteria
• More than 5000/mmc cells of T-PLL phenotype in peripheral blood or bone marrow. • T-cell clonality (by polymerase chain reaction for *TCRB/TCRG*, or by flow cytometry). • Abnormalities of 14q32 or Xq28 or expression of *TCL1A/B* or *MTCP1*.	• Abnormalities involving chromosome 11 (11q22.3; *ATM*). • Abnormalities in chromosome 8. • Abnormalities in chromosomes 5, 12, 13, 22, or complex karyotype. • Involvement of T-PLL specific site (splenomegaly, effusions).

Differential Diagnosis

T-cell neoplasms with leukemic presentation other than T-PLL can be ruled out by morphology evaluation and flow cytometry assays. The most relevant diseases that can resemble T-PLL are represented by: T-cell acute lymphoblastic leukemia (T-ALL), leukemic dissemination of PTCL, T-LGL, SS, and ATLL. Table 89.4 summarizes the criteria to accomplish a correct differential diagnosis.

Therapy

Since the disease is usually symptomatic, clinically aggressive, and rapidly progressive, a prompt initiation of a systemic treatment is required. On the other hand, 20% to 30% of patients demonstrate an initially stable or slowly progressive disease ("inactive" T-PLL). In these cases, a period of close observation is recommended. However, almost all "inactive" T-PLL turn into "active" (symptomatic) disease within 1 to 2 years.

Symptomatic T-PLL is defined as (at least one of the following): presence of constitutional symptoms (fatigue, unintentional weight loss of >10% of normal body weight within 6 months, drenching night sweats or fever >38°C without signs of infection); symptomatic bone marrow failure (hemoglobin <10 g/dL and/or platelet count <100,000/mmc); rapidly enlarging lymph nodes, spleen, and liver (>50% enlargement within 2 months, or diameter doubling within 6 months, or symptomatic organomegaly); increasing lymphocytosis (>50% within 2 months when lymphocytes are >30,000/mmc or doubling time shorter than 6 months); extranodal involvement (organ infiltration, peritoneal or pleural effusion, central nervous system involvement).

Intravenous alemtuzumab, a humanized anti-CD52 antibody, is the first-line treatment of choice, yielding up to an 80% of complete response (CR) in treatment-naïve patients.[4] Of note, this treatment is frequently complicated by cytomegalovirus (CMV) reactivations, sometimes requiring adequate antiviral treatment. Thus, CMV-DNA monitoring during the courses is strongly recommended.[5] Prophylaxis for *Pneumocystis jirovecii* is also indicated.

Although prolonged responses to alemtuzumab have been described, all patients have a tendency to relapse; therefore, a consolidation with an allogeneic stem cell transplantation in first remission may offer a chance for a better long-term survival, when feasible. Autologous stem-cell transplantation may also be beneficial for patients, but it does not result in a cure. Retreatment with alemtuzumab at disease relapse is feasible if remission duration is longer than 6 months. However, the emergence of a CD52$^-$ phenotype clearly indicates a mechanism of resistance to alemtuzumab. Purine-analogues, such as pentostatin, cladribine, nelarabine, or fludarabine, may be a good treatment alternative, with some evidence of activity in T-PLL.[6,7] Pentostatin, in particular, is the agent of choice when suboptimal responses to alemtuzumab are seen.

Experiences with targeted agents, like the combination of venetoclax and ibrutinib, are now ongoing. Reports exist on salvage treatment with JAK inhibitors in patients with multi-treated T-PLL harboring JAK mutations.

TABLE 89.4 **Most Relevant Differential Diagnoses Among T-Cell Neoplasms With Leukemic Presentation**

Disease	Morphology	Immunophenotype
T-PLL	High nuclear-cytoplasmic ratio, round or oval and irregular or convoluted nuclei, single prominent nucleolus, agranular cytoplasm, frequently with blebs	TCL1$^+$ (>90%), CD3$^+$ (>80%), CD4$^+$ (60%), CD5$^+$ (100%), CD7$^+$ (>90%), CD8$^+$ (15%), CD4$^+$CD8$^+$ (25%)
T-ALL	Blasts with high nuclear-cytoplasmic ratio, rather condensed chromatin, inconspicuous nuclei, scarce agranular cytoplasm	TdT$^+$, CD1a$^+$
Leukemic PTCL	Highly pleomorphic mature lymphocytes	TCL1$^-$
T-LGL	Round eccentric nucleus with dense chromatin, abundant pale cytoplasm with numerous azurophilic granules	CD8$^+$, CD57$^+$, CD16$^+$
SS	Convoluted (cerebriform) nucleus with condensed chromatin and sometimes evident nucleoli, agranular cytoplasm, sometimes with a ring of vacuoles	CD7$^-$, CD4$^+$, CD25$^+$
ATLL	Highly pleomorphic mature lymphocytes, sometimes with a characteristic lobated nucleus (flower cells)	CD4$^+$, CD25$^+$, HTLV1$^+$

Treatment response criteria are outlined in Table 89.5: both clinical and laboratory parameters need to be considered to define the depth of the response. A general recommendation on adequate timing to assess a response cannot be made, as response kinetics appear different depending on the agents used (chemotherapy *versus* antibodies).

Prognosis

Response to alemtuzumab is the main outcome predictor: non-responders have a median survival of only 4 months. Five-year overall survival (OS) is nearly 21%, with high white cell counts, older age, and short lymphocyte doubling time being adverse prognostic factors. Reports exist on the possible development of EBV-driven non-Hodgkin lymphomas in patients receiving alemtuzumab for T-PLL: an aggressive clinical course and rapid development of nodal lesions in an otherwise responding T-PLL patient always deserve attention (with imaging studies and nodal biopsy).

PERIPHERAL T-CELL LYMPHOMAS

This section reviews some general aspects regarding the epidemiology of PTCL and the shared mechanisms underlying the lymphomagenesis of these entities. Specific disease subtypes are reviewed especially in terms of their biopathology, clinical peculiarities, and prognostic tools. First-line treatment approaches are discussed at the end, with a particular focus on the management of some specific subtypes, bearing in mind that the vast heterogeneity of these diseases, coupled

TABLE 89.5 Treatment Response Criteria in T-PLL

Group and Parameter	Complete Response (All Criteria to Be Met)	Partial Response (≥2 Criteria in A and ≥1 in B)	Stable Disease (All Criteria to Be Met)	Progression (≥1 Criterion in A or B to Be Met)
Group A				
Lymph nodes	Long axis <1 cm	Decrease ≥30% in SLD	Reduction <30% or increase ≤20%	Increase >20% in SLD
Spleen	Spleen size <13 cm	Decrease ≥50% in vertical length	Reduction or increase <50%	Increase ≥50%
Symptoms	None	Any	Any	Any
Circulating lymphocytes	<4000/mmc	≤30,000/mmc with decrease ≥50%	>30,000/mmc or change <50%	Increase ≥50%
Marrow	T-PLL cells <5%	Any	Any	Any
Any other site	No involvement	Any	Any	Any
Group B				
Platelets	≥100,000/mmc	≥100,000/mmc or increase ≥50%	Change <50%	Decrease ≥50%
Hemoglobin	≥11 g/dL	≥11 g/dL or increase ≥50%	<11 g/dL or change <50% or reduction <2 g/dL	Decrease ≥2 g/dL
Neutrophils	≥1500/mmc	≥1500/mmc or increase ≥50%	Change <50%	Decrease ≥50%

SLD, Sum of long-axis diameters of up to three target lesions.

with their rarity, has always hampered the design and development of adequately powered clinical studies able to provide strong treatment evidence. Recommended strategies for the treatment of relapsed and refractory disease, along with a focus on newly available single agents and innovative combinations, is also provided.

Epidemiology of Peripheral T-Cell Lymphomas

The most common entity is PTCL-NOS, which includes a heterogenous group of mature T-cell lymphomas representing up to a third of all PTCL. AITL is the second most common subtype, accounting for 15% to 30% of all PTCL, according to different case series. ALCL represents nearly 15% of all PTCL. Among extranodal entities, ENKL accounts for nearly 10% of all PTCL, followed by primary intestinal T-cell lymphomas (5% to 6% of all PTCL), HSTCL (2% of all PTCL), and SPLTCL (<2%). Some lymphomas display a peculiar geographical distribution: the broad category of PTCL-NOS is uniformly distributed in Western countries, where it represents the most frequent category. Similarly, AITL is more frequently diagnosed in Europe, although incidence varies across regions.[8,9] It should be noted, however, that many cases previously characterized as PTCL-NOS can be reclassified into more recent 2017 WHO-recognized categories. Such update of classification may affect the real epidemiology of AITL and PTCL-NOS. Part of PTCL-NOS cases display a T_{FH} phenotype, and thus require to be more correctly classified as T_{FH}-derived PTCL.[10] ENKL is mostly observed in Asia and Central-South America and shows higher prevalence among Hispanic people, American Indians, Asians, and Pacific Islanders (with a frequency of 15% among all PTCL). Likewise, ALCL seems to be more frequent in Hispanic people and American Indians than in Black or non-Hispanic people.

A family history of hematologic disorders, genetic background, viral infections, occupational and environmental exposure, dietary intake, immune-mediated diseases, and persistent immunosuppression have all been considered relevant risk factors for the development of PTCL.

Shared Pathogenetic Mechanisms

As it happens with all lymphoid neoplasms, the accumulation of genomic defects over time leads to an altered balance between genomically aberrant lymphocytes and normal host cells, ultimately determining the neoplastic transformation of the tissue and the clinical manifestation of the disease. Multiple mechanisms have been described as responsible for the T-cell transformation into an overt neoplasm.[2] Given the wide heterogeneity of PTCL, not all the following mechanisms apply to each disease category, although some shared pathogenetic steps may be identified; most PTCL, in fact, demonstrate intrinsic defects which end up with the deregulation of multiple signaling pathways. Six shared mechanisms are briefly described in this paragraph; peculiar genomic or epigenomic changes specifically correlated with well-defined disease entities are instead described separately.[2]

1. **Role of the TCR signaling**. Some PTCL acquire defects that uncouple the TCR signaling from the TCR engagement. Somatic mutations in co-stimulatory molecules (such as CD28, as seen in AITL) or downstream components of the signaling cascade (PI3K-AKT signaling, NFκB signaling), structural alterations (as it happens with ITK-SYK fusion protein in PTCL-NOS and with ALK-chimeric proteins in ALCL-ALK^{+}) or loss of TCR-negative regulators (like the phosphatase DUSP22, which works as an onco-suppressor) all contribute to the uncontrolled TCR activation, fostering a neoplastic phenotype.
2. **Epigenomic changes**. Epigenetic dysregulation is a hallmark of several PTCL, mainly those arising from T_{FH} cells, where *TET2*, *IDH2*, and *DMT3A* mutations are characteristically detected. Epigenetic alterations lead to a deregulated expression of genes that promote T_{FH} differentiation and sustain a transformed phenotype synergistically with additional defects. Moreover, they contribute to an increased self-renewal capacity of stem cells and hematopoietic progenitors and alter their terminal differentiation. Of note, mutations of *TET2* and *DNMT3A* are also detected in hematopoietic progenitors of ageing people and in clonal hematopoiesis processes, putting those individuals at greater risk of neoplasm, mainly myeloproliferative diseases. Importantly, patients with *TET2* or *DNMT3A*-mutated AITL who later developed a myelodysplastic or myeloproliferative syndrome showed the same mutation in their hematopoietic stem cells and in the neoplastic myeloid cells as well, thus leading to postulate that these mutations constitute a pre-malignant status that precedes the malignant transformation of both myeloid and lymphoid cells.
3. **Deregulated activation of the JAK-STAT pathway**. The JAK-STAT pathway controls cell growth arrest and apoptosis and its

constitutive activation results in cells that are independent of (or at least less dependent on) extracellular signals. Together with the loss of negative regulators (e.g., due to mutations of *PTPN2* or *PTPN6*-encoded phosphatases), cells become insensitive to inhibitory signals, thus being prone to a malignant transformation. The JAK-STAT pathway is commonly deregulated in PTCL and mutations in the JAK and STAT system in T-cell neoplasms have been detected in the SH2 domain of STAT3 and STAT5 and in the pseudokinase domain of JAK1 and 3. This has been particularly observed in ALCL, PTCL-NOS, CTCL, ENKL, and rarer extranodal entities.[11]

4. **Metabolic dysregulation**. Metabolic reprogramming of cancer cells also contributes to tumorigenesis and to the maintenance of the tumor itself: high glucose uptake, high glycolytic activity, nucleotide, and membrane phospholipids synthesis promote proliferation and sustain PTCL cells under stress conditions. These mechanisms have been particularly highlighted in ALCL, where they seem to be correlated to the activity of ALK-fusion proteins along with the constitutive activation of certain regulatory proteins (e.g., STAT3).
5. **Microenvironmental interactions**. Neoplastic cells in PTCL highly depend on their microenvironment: TCR activation and secretion of cytokines through paracrine and autocrine stimulations (e.g., IL-4, IL-5, IL-13, and VEGF) are of great importance for tumor progression and maintenance and explain the majority of systemic symptoms patients affected by PTCL complain of. Moreover, the successful growth and survival of neoplastic cells is modulated by pro-tumorigenic signals from surrounding elements (e.g., functional recruitment of surrounding suppressor regulatory T_{reg} cells operated by PTCL-NOS and ALCL) and by decreased immunogenicity due to loss of HLA class I protein or via the interaction between programmed death-1 (PD-1) and its ligand PD-L1, the latter being highly expressed on the surface of ALCL-ALK$^+$ and ENKL cells.
6. **EBV-mediated oncogenesis**. Apart from B cells, EBV may infect an early precursor lymphoid cell which ultimately can differentiate into a B, T, or NK cell. A spectrum of EBV$^+$ T-cell lymphoproliferative neoplasms is now recognized, ranging from aggressive ENKL to more indolent cutaneous lymphoproliferative diseases. The pathogenesis of these disease entities and how EBV$^+$ T and NK cells progress and ultimately escape from immunosurveillance is not entirely clear. It can be postulated that in ENKL EBV$^+$ T and NK cells derive from the clonal expansion of a pre-malignant EBV-infected normal T or NK cell, which likely occurs in a unique genomic background (this may be an explanation of the much higher incidence of this lymphoma in Asia).

Diagnosis and Staging

The diagnosis of PTCL is always established on the biopsy of the involved tissue, which is mainly represented by a lymph node. However, virtually any extranodal sites may also be the site of biopsy: liver, small intestine, and skin are among the mostly involved extralymphatic tissues. The review of all slides and of formalin-fixed paraffin embedded tissue by a pathologist with expertise in T-cell lymphoma is always encouraged. Generally, diagnostic accuracy is very good for ALCL-ALK$^+$, but agreement is lost in case of other lymphoma subtypes, with a rate of concordance of about 75% for the most common subtype, PTCL-NOS.

Molecular studies may be helpful under certain circumstances to clarify or refine the diagnosis: at present, however, no molecular markers specifically dictate or guide treatment decisions. The sole demonstration of T-cell clonality through the assessment of TCR rearrangement alone is not sufficient for diagnosis, as this may be seen with reactive and inflammatory processes.

The clinical approach to the patient is described in the box on Clinical Approach to a Patient Affected by PTCL and Staging Recommendations.

CLINICAL APPROACH TO A PATIENT AFFECTED BY PTCL AND STAGING RECOMMENDATIONS

1. Accurate past medical history: concomitant diseases (e.g., celiac disease or concomitant hematological neoplasms); occupational exposure.
2. Recent medical history, particularly focused on lymphoma-related symptoms (recent weight loss, fever, night sweats).
3. Performance status assessment.
4. Physical examination, which must include the evaluation of Waldeyer's ring, nasopharynx, node-bearing areas, liver and spleen, thoracic auscultation, and a full skin inspection.
5. Laboratory: complete blood count with differential counts (including the examination of a peripheral blood smear, when indicated), liver and renal function tests, lactate dehydrogenase. Reticulocytes and bilirubin (complete and fractionated) are useful markers in case of suspect hemolysis, which may be associated with some PTCL cases (mainly AITL). Direct Coombs test is also necessary to establish a diagnosis of autoimmune hemolytic anemia.
6. Staging procedures: computed tomography (CT) scan of neck, chest, abdomen, and pelvis with intravenous contrast and unilateral bone marrow trephine biopsy. ^{18}F-fluorodeoxyglucose positron emission tomography (PET) scan is not mandatory but may be helpful (see box on The Role of PET Scan as a Staging Tool in Peripheral T-Cell Lymphomas).

THE ROLE OF PET SCAN AS A STAGING TOOL IN PERIPHERAL T-CELL LYMPHOMAS

- ^{18}F-fluorodeoxyglucose (FDG) PET scan is not mandatory for disease staging, although it has proven to be helpful in detecting FDG-avid nodal or extranodal lesions that can be missed by a CT scan evaluation.
- PET scan may change the disease stage in no more than 5% of patients at diagnosis as compared to CT. This change generally does not translate into treatment modification or intensification.
- PET positivity found at the end of induction treatment and in patients who have received autologous stem cell transplantation is a strong predictor of reduced survival.
- Maximum standard uptake values in patients with PTCL are lower (and much more heterogeneous) than in aggressive B-cell counterparts, and usually less pronounced for extranodal lesions than for lymph node localizations of the disease.

Like nodal B-cell lymphoma, PTCL are staged according to the Ann Arbor staging system. Computed tomography (CT) scan of neck, chest, abdomen, and pelvis with contrast and a bone marrow trephine biopsy are requested to accomplish disease staging. The role of positron emission tomography (PET) during staging and response assessment is briefly reviewed in the box on The Role of PET Scan as a Staging Tool in Peripheral T-Cell Lymphomas.

Peripheral T-Cell Lymphoma, Not Otherwise Specified

PTCL-NOS remains a category of biologically and clinically heterogeneous diseases which cannot be further classified into any other of the existing entities defined by the current WHO classification. As a consequence, this disease is heterogeneous, as it displays a broad cytological spectrum and a multiplicity of molecular aspects. Gene expression profile studies have shown that many of these cases resemble ALCL, adult T-cell leukemia/lymphoma, AITL, or ENKL; in some cases, molecular markers help define a peculiar T_{FH} origin.[1,10,12]

PTCL-NOS is the most common subtype, accounting for at least 25% to 30% of PTCL. Its prevalence is geographically variable, given that it is equally spread across North America and Europe (34% of PTCL cases), and slightly less diffused in Asia, accounting for 22% of PTCL cases.

Morphology and Pathobiology

The normal architecture of the lymph node appears effaced and neoplastic elements show a variable morphology, ranging from small cells with irregular nuclei to large cells with prominent nucleoli and mitotic figures. An inflammatory background is often present including small reactive lymphocytes, eosinophils, plasma cells, and epithelioid histiocytes. Epithelioid histiocytes are particularly numerous in the *lymphoepithelioid variant* (also termed Lennert lymphoma). Neoplastic cells stain positively for CD2, CD3, CD5, and CD7, although CD5 and/or CD7 may be frequently lost. The expression of CD4 and CD8 is also variable. The ALK protein is always negative and given that CD30 can be expressed in more than 75% of the neoplastic cells, the differential diagnosis with an ALCL-ALK$^-$ constitutes a diagnostic challenge. The proliferation index according to Ki-67 is usually high and rates exceeding 70% are associated with a worse prognosis (Fig. 89.3).

Rare cases of PTCL-NOS express the cytotoxic granule-associated proteins (perforin, granzyme-B, and TIA-1), and this specific pattern has been observed in the lymphoepithelioid variant.

Significant improvements have been made in delineating specific biological and prognostic subgroups within the PTCL-NOS spectrum: in particular, two major molecular clusters have recently been delineated: one subgroup shows a high expression of *GATA3* and an enrichment of gene signatures related to cell proliferation (*MYC*), mammalian target of rapamycin (mTOR), and β-catenin; the other significantly expresses *TBX21* (*T-bet*) and is enriched of interferon (IFN)- γ and NFκB-induced gene signatures. *GATA3* regulates T-helper 2 cell differentiation, whereas *TBX21* polarizes cells to a T-helper 1 and cytotoxic T-cell phenotype. This distinction has an important prognostic correlate, as *GATA3* expression confers a poor prognosis, with a 5-year OS of 19%. On the contrary, cases with a *TBX21* signature display more favorable outcomes, and may display a 5-year OS of 38%.[13]

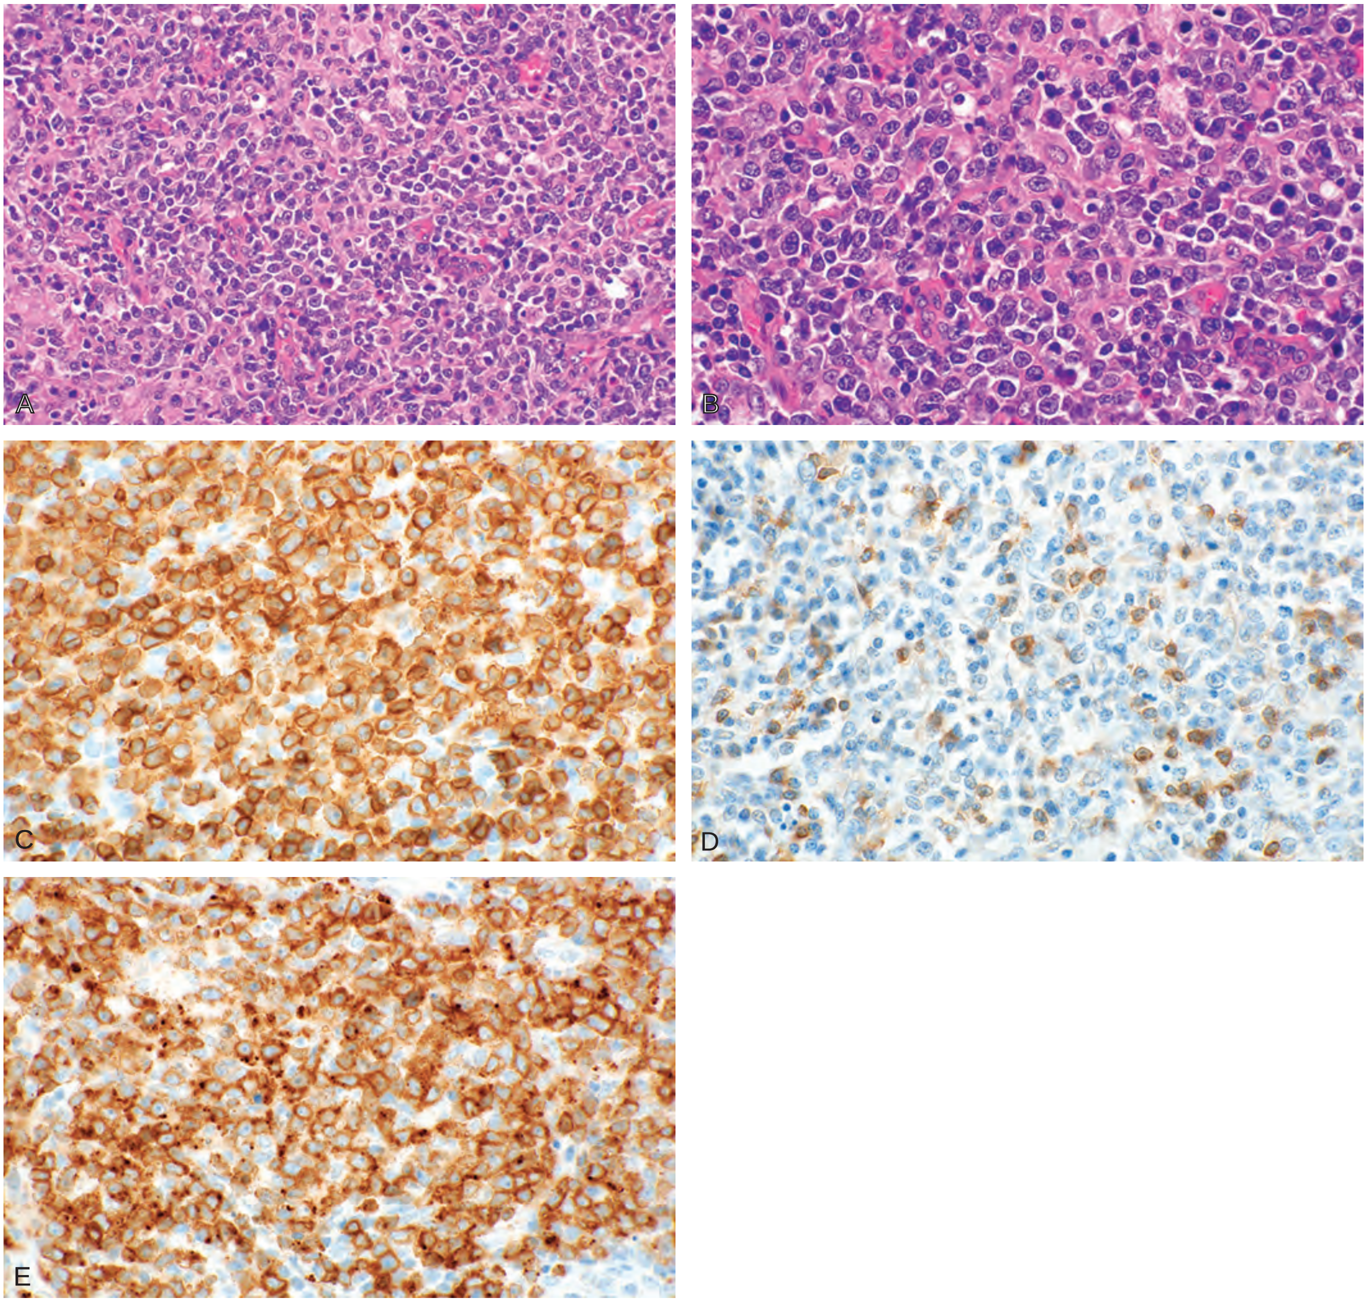

Figure 89.3 Peripheral T-cell lymphoma, not otherwise specified, lymph node biopsy, hematoxylin-eosin staining at lower (40×, panel A) and higher (50×, panel B) magnification. Immunohistochemical staining for CD4 (panel C), T-cell receptor βF1 (panel D), and δ (panel E).

Recurrent genetic abnormalities of *TET2*, *IDH2*, *DNMT3A*, *RHOA*, and *CD28* mutations may be observed in cases of PTCL-NOS that manifest a T_{FH} phenotype, as it happens with AITL: for this reason, the former *follicular variant* of PTCL-NOS has been moved to the new T_{FH} lymphoma category in the most recent (2017) WHO classification.[14]

Clinical Manifestations

Adult patients are mostly affected, as median age at presentation is 60 years. Children can be affected, albeit rarely. The disease shows predilection for males, with a male-to-female ratio of 2:1. Nodal involvement is the most relevant clinical feature at diagnosis, although any organ can be involved, including bone marrow, liver, spleen, gastrointestinal tract, and skin (the latter being the most widely involved, 16% of the cases). Synchronous nodal and extranodal involvement is not infrequent. Nearly 70% of cases present with advanced stage (III-IV according to the Ann Arbor staging system); lymphoma-related symptoms, LDH elevation and poor performance status may be documented in half of the patients.

Prognosis

The International Prognostic Index (IPI), widely applied in aggressive B-cell lymphomas, retains its association with treatment outcomes in T-cell neoplasms:[15] patients with low score (0 to 1 prognostic factors) have a 5-year OS of 50%, in contrast with those with high score (4 to 5 prognostic factors), whose 5-year OS is only 11%. Newer scores have been specifically built up for PTCL-NOS patients: the Prognostic Index for PTCL-NOS (PIT) and the modified PIT (m-PIT): they share age (>60 years), Eastern Cooperative Oncology Group (ECOG) performance status (>1) and LDH elevation with IPI; PIT also takes into account bone marrow infiltration, while m-PIT integrates the expression of the proliferation-associated protein Ki-67.[16,17] A fourth prognostic index derived from the International T-cell Lymphoma Project (ITCLP) indicates age (>60 years), ECOG (>1), and thrombocytopenia (<150,000/mmc) as the three most relevant parameters for prognostic stratification (Table 89.6).[18] Importantly, all these prognostic scores have been validated in subpopulations treated with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) or at least an anthracycline-containing regimen. The four scores divide PTCL-NOS patients in 3 (m-PIT, ITCLP) or 4 (IPI, PIT) prognostic categories: the lower-risk group, whatever score is used (score 0 to 1 for IPI and m-PIT, score 0 for PIT and ITCLP) emerges as a clearly separated category and shows better outcomes than all the other risk groups (Table 89.7.)

TABLE 89.6 **Variables Used in the Calculation of Relevant Prognostic Scores**

Angioimmunoblastic T-Cell Lymphoma

AITL is a rare disease, which accounts for only 1% to 2% of non-Hodgkin lymphomas and 15% to 20% of PTCL. Disease incidence is higher in Europe (29% of all cases of PTCL), followed by Asia (18%) and North America (16%); the reasons for this heterogeneity in different parts of the world is largely unexplained.[19]

AITL is a T_{FH}-derived neoplasm that originates from follicular helper T-lymphocytes: these cells are normally present in lymphoid follicles and are mainly implicated in the germinal center reaction in close collaboration with germinal center B-lymphocytes. Given that a number of recurrent mutations and a characteristic gene signature characterize a significant proportion of AITL cases, as well as some cases of PTCL-NOS, which manifest a T_{FH} phenotype, the 2017 revision of the WHO classification unifies under a common heading AITL, follicular T-cell lymphoma and nodal PTCL with T_{FH} phenotype.[1,2]

AITL is a disease of the elderly, with a median age of 65 years at presentation, with no gender predilection.

Morphology and Pathobiology

The architecture of the affected lymph node is effaced by a T-cell infiltrate of polymorphous lymphocytes that extends beyond the nodal capsule and characteristically spares the subcapsular sinus, which appears open and dilated. Regressed follicles may be appreciated, especially in earlier stages of the disease, indicating that the disease arises in association with germinal centers, extending to extrafollicular regions as it progresses. Neoplastic cells are admixed with reactive small lymphocytes, eosinophils, plasma cells, and an abundant amount of follicular dendritic cells, which represent the accompanying non-neoplastic populations. Scattered large $CD20^+$ immunoblastic cells, usually staining positively for EBV-encoded RNA (EBNA), are found in most cases. The prominent proliferation of high endothelial venules with a tendency to arborization is

TABLE 89.7 **Prognosis of Aggressive Peripheral T-Cell Lymphomas According to the Most Widely Used Prognostic Scores***

Disease	Score	5-year OS (%)		5-year FFS (%)

SPTCL	(**)	60		30–40	

OS, overall survival; *FFS*, failure-free survival. See text for disease and prognostic scores abbreviations.

*"Low score" means score 0 to 1 for IPI, score 0 (group 1) for PIT, and score 0 to 1 for PIA. "High score" means score 4 to 5 for IPI, score 3 to 4 (group 4) for PIT, and score ≥2 for PIA.

**IPI (or any other prognostic score) not relevant for prognostic stratification of patients.

a characteristic feature of AITL. T-cell-associated antigens are demonstrated by immunohistochemistry, although neoplastic cells may show aberrant phenotypes: CD3, CD4, CD10, PD-1, and sometimes BCL6 are the most frequently encountered antigens, whereas CD5 and CD7 are frequently defective (Fig. 89.4).

Several genes overexpressed in AITL (like *CD200*, *PDCD1*, *CD40L*, *NFATC1*, *LIF*) have been reported as overexpressed in T_{FH} compared to other T-cell subsets, thus supporting the AITL derivation from T_{FH} cells. The detection of at least three T_{FH}-associated molecules by immunohistochemistry (CD10, BCL6, PD-1, CXCL13, CCR5, SAP, ICOS), which is a surrogate for gene expression profiling, is considered sufficient to suggest the derivation of a given T-cell neoplasm from T_{FH}. This is generally true for AITL, but also for a proportion of PTCL-NOS, as said. The cellular derivation of AITL from T_{FH} cells provides an explanation to the peculiar pathological and biological features of the disease, like the expansion of B-lymphocytes, the intimate association with germinal centers in early disease stages, the associated immune deficiency and the deregulated immunoinflammatory response that characterizes its clinical course.[20]

The AITL mutational landscape is complex: *TET2*, *IDH2*, *DNMT3A*, and *RHOA* are among the most relevant mutated genes, possibly with a role in lymphomagenesis.[21–25] Mutations of *TET2* are the most prevalent among AITL (half to three quarters of the cases) and generally correlate with advanced-stage disease, high IPI, thrombocytopenia, elevated LDH, and shortened survival. *TET2* and *DNMT3A* mutations seem to occur at an early stage of hematopoietic differentiation and may represent early events of lymphomagenesis. Mutations of *IDH2* at R172 are also characteristic of AITL and tend to co-occur with *TET2* mutations: they define a unique subgroup of AITL with distinct gene expression, and *IDH2*/*TET2* double-mutant cases display a significantly more polarized T_{FH} phenotype. Somatic *RHOA* mutations have also been

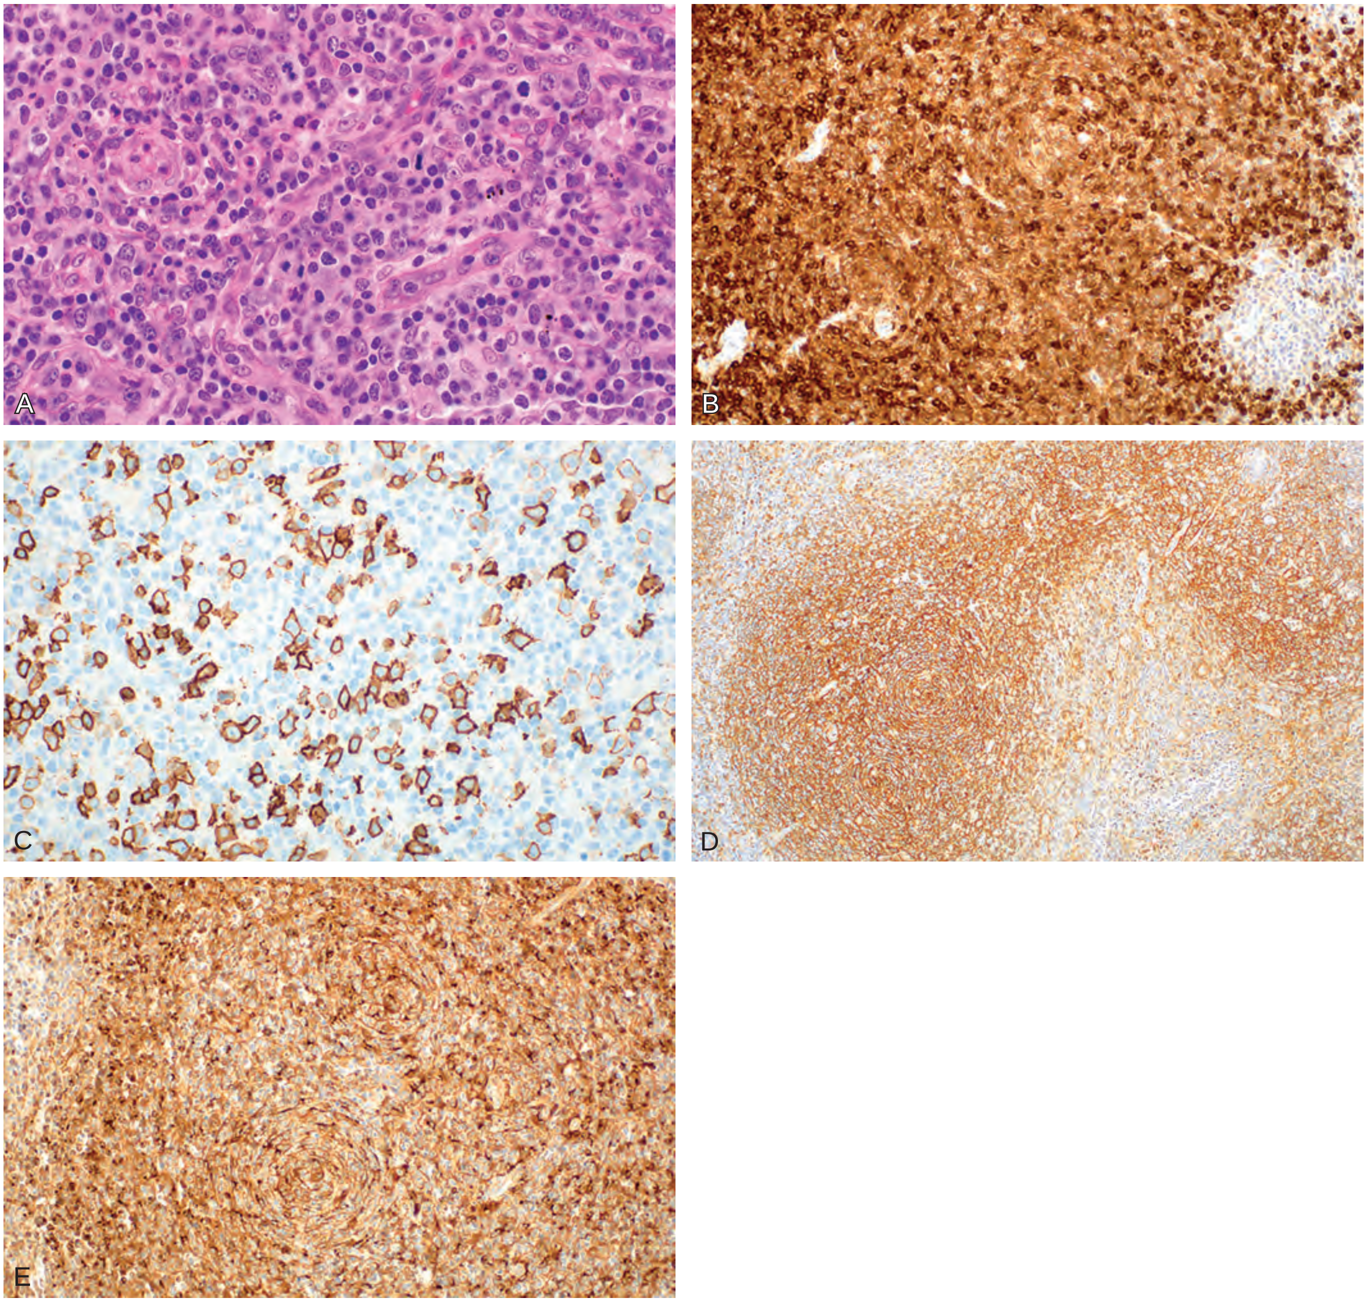

Figure 89.4 Angioimmunoblastic T-cell lymphoma, lymph node biopsy, hematoxylin-eosin staining (panel A). Positive immunostaining for CD10 (panel B). described in nearly 70% of AITL, constantly co-occurring with *TET2* and very often with *DNMT3A* mutations: RHOA is activated downstream of TCR engagement in mature T-lymphocytes, and when mutated it shows an impaired GTP-ase function that also inhibits its wild-type form. The coexistence of these mutations occurring at different times of a multistep model of lymphomagenesis, the co-operation of the aberrant encoded proteins, along with other mutations affecting genes related to TCR signaling that deregulate its activation may co-operate in the pathogenesis of AITL and other T_{FH}-derived PTCL.

Clinical Manifestations

This disease behaves aggressively: at least 70% of patients display systemic symptoms at onset, including fever and weight loss, and the disease presents with advanced stage in about 75% of cases. Generalized lymphadenopathy along with a fluctuating skin rash (due to cutaneous dissemination) constitute a distinctive clinical presentation. Hepato-splenomegaly may be found in one third of cases and the bone marrow is infiltrated in nearly half of patients. Peripheral edema, pleural or peritoneal effusion, joint pain, or cold agglutinin disease can be associated phenomena. Autoimmune cytopenia(s)—above all Coombs-positive autoimmune hemolytic anemia—are also a common feature of the disease: they often respond to lymphoma-directed therapies, and their evolution parallels the one of the lymphoma itself.

Laboratory Manifestations

A specific laboratory abnormality associated with AITL is the detection of a polyclonal hypergammaglobulinemia in 30% to 50% of cases, sometimes with the presence of a monoclonal serum immunoglobulin. Hypergammaglobulinemia is probably related to the fact that the tumor cells are derived from T cells with a specific B-cell helper capacity. This also explains the frequent detection of autoimmune markers, such as rheumatoid factor, circulating immunocomplexes, and anti-smooth muscle antibodies.

Prognosis

According to retrospective series, when patients are treated frontline with anthracycline-containing combination chemotherapy, the 5-year OS for those with an IPI score of 0 to 1 is 56% and 25% for patients with a score of 4 to 5. An alternative prognostic model based on age (>60 years), performance status (>2), extranodal site involvement (≥2 sites), presence of B-symptoms, and platelet count (<150,000/mmc) has been recently proposed (prognostic index for AITL, PIAI) and was more predictive of OS than IPI in patients with lower (score 0 to 1) and higher (score 3 to 5) risk.[19] Anemia (hemoglobin <12 g/dL), mediastinal lymphadenopathy, white blood cell count (>10,000/mmc), and immunoglobulin A concentration (>400 mg/dL) (see Table 89.4) have also shown a significant impact on prognosis.

Anaplastic Large-Cell Lymphoma

ALCL should be conceived as a group of T-cell non-Hodgkin lymphomas with unifying pathological characteristics although displaying heterogeneous clinical and genetic features. The current WHO classification includes four distinct ALCL entities.[1] Two of them are of nodal origin and are distinguished by the expression (or not) of the ALK protein into an ALCL-ALK$^+$ and an ALCL-ALK$^-$, the latter being no longer conceived as a provisional subcategory, but rather defined as a specific disease entity. This distinction is of importance, as the two entities display a heterogeneous clinical behavior, a different prognosis when treated frontline with conventional therapy, and are managed differently. The third entity has an exquisitely cutaneous presentation, and thus it is termed primary cutaneous ALCL (pcALCL): for this reason, it is discussed in the cutaneous T-cell lymphoma section, among the primary cutaneous CD30$^+$ T-cell lymphoproliferative disorders. The last entity is inherently associated with breast prostheses and therefore termed breast implant-associated (BIA) ALCL, nowadays considered as a new provisional category.

ALCL represents nearly 15% of all PTCL and accounts for approximately 2% of all adult non-Hodgkin lymphomas and 10% to 30% of childhood non-Hodgkin lymphomas.[8,9] Taken as a whole, it shows a bimodal age of presentation with a peak in children and young adults and a second peak around the age of 60. More precisely, ALCL-ALK$^+$ is mostly diagnosed in the first three decades of life; on the other hand, ALCL-ALK$^-$ usually affects adults, with a median age of 54 to 61 years. BIA-ALCL typically presents approximately one decade after implant placement, with a median age of 52.5 years.

Morphology and Pathobiology

ALCL is histologically characterized by the presence of sheets of *hallmark cells*: these are large anaplastic cells with round to kidney-shaped nucleus, central nucleolus, and variably basophilic cytoplasm. Different morphological variants of ALCL-ALK$^+$ are recognized: the *common type* (diffuse growth and sinus invasion), the *lymphohistiocytic type* (with hallmark cells hidden within a reactive lymphohistiocytic background), the *small cell type* (the neoplastic cells are mainly of small size), and the *Hodgkin-like type* (characterized by nodular growth and fibrosis which suggest a nodular sclerosis variant of a classical Hodgkin lymphoma). All morphologic variants can be represented in the same lymph node. ALCL-ALK$^-$ more commonly presents with a *common type* pattern of growth.

The phenotype is often aberrant, lacking the common leukocyte antigen (CD45) and some or all the T-cell associated markers (CD3, CD2, CD5 e CD7) in up to 30% of cases. ALCL are more frequently of CD4 origin, but CD8$^+$ or CD4$^-$/CD8$^-$ cases can occur. The most peculiar immunophenotypic feature is the wide and strong expression of the lymphoid activation molecule CD30. Additionally, ALCL-ALK$^+$ shows a nuclear positivity for the ALK protein (Fig. 89.5).

ALCL-ALK$^+$ harbors the t(2;5)(p23;q35) translocation, which juxtaposes the *ALK* gene to the *NPM* (nucleophosmin) gene on chromosome 5.[26] The *ALK* gene encodes for a tyrosine-kinase receptor belonging to the insulin receptor superfamily, which is usually silent in normal lymphoid cells and absent in normal (but few cerebral) cells. The NPM protein is expressed at a nuclear level in normal cells and acts as a shuttle protein from the nucleus to the cytoplasm. This translocation produces an *ALK-NPM* fusion gene capable of encoding for a novel chimerical aberrant protein absent in normal tissues. The NPM side of the newly produced molecule resides both in the nucleus and the cytoplasm, where it can be detected with specific commercially available antibody. Translocation variants have been described, which always involve the *ALK* gene on chromosome 2. The aberrant NPM-ALK protein, as well as the fusion proteins resulting from variant translocations, constitutively activate downstream effectors, including phospholipase Cγ, PI3K-AKT, Ras-ERK, JAK3-STAT3, and the Sonic hedgehog signaling pathways, all of which lead to prolonged survival and proliferative advantage of the neoplastic cells.

The molecular features of ALCL-ALK$^-$ are far less known. Approximately 30% of cases harbor rearrangements of *DUSP22* as a consequence of the t(6;7) translocation: this alteration identifies a subset of patients with more favorable outcomes, closely resembling ALCL-ALK$^+$, as the 5-year OS approximates 90%.[27] Conversely, rearrangements of the *TP63* gene, marked by inv(3) and identified in 8% of the cases, are associated with very poor outcomes, as the 5-year OS is only 17%. Other genetic aberrations, including *PDRM1/BLIMP1*

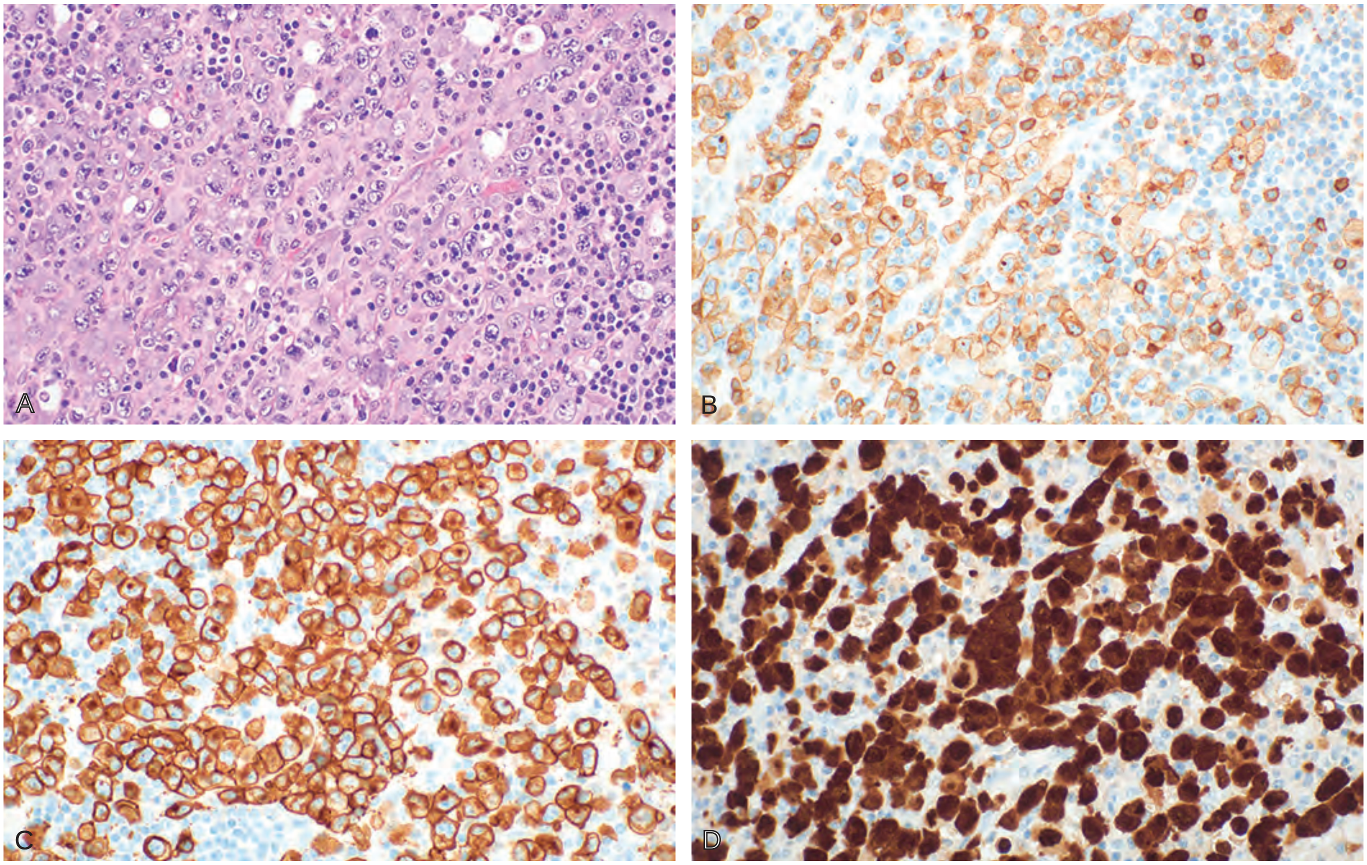

Figure 89.5 Anaplastic large-cell lymphoma, lymph node biopsy, hematoxylin-eosin staining (panel A). Immunohistochemistry for CD5 (panel B). CD30 is highly expressed on neoplastic elements (panel C). Expression of the anaplastic lymphoma kinase (ALK) by immunohistochemistry (panel D).

gene inactivation and the 17p13/*TP53* genetic loss, define a poor prognostic clinical entity.

BIA-ALCL does not harbor recurrent translocations found in other ALCL-ALK$^-$; conversely, activation of STAT3 is common and recurrent mutations of *STAT3*, *JAK1*, or *SOCS1* have been described. There is a close association of this disease with textured rather than smooth breast implants; implant surface texturing may promote bacterial proliferation, with lymphocyte activation and chronic inflammation due to a bacterial biofilm infection around the implant. The associated chronic T-cell stimulation could promote lymphomagenesis.[28]

Clinical Manifestations

Clinical presentation of ALK$^-$ and ALK$^+$ subtypes is similar. About 70% of patients with ALCL present with advanced-stage disease at diagnosis. In one third of patients, peripheral or abdominal nodal disease is associated with bone marrow infiltration or extranodal involvement, more commonly at the skeleton, lungs, and liver. Advanced-stage disease is documented in at least 60% of cases, and lymphoma-related symptoms—mainly fever—can be often encountered at onset.

BIA-ALCL first presents as a seroma fluid that accumulates between the implant and the surrounding fibrous capsule. More than 90% of the cases are localized at the time of diagnosis (stage I–II), sometimes with regional adenopathy, thus suggesting that surgical capsulectomy may be curative. Alternatively, the disease may develop as a growing mass, eventually with distant dissemination. The clinical course varies widely from apparent spontaneous resolution to systemic treatment-resistant disease and death.[29]

Prognosis

Outcomes are highly variable depending on the specific disease subset: this indicates why a clear cut among subtypes is necessary. The 5-year OS rate ranges between 70% and 86% for ALCL-ALK$^+$ and between 30% and 49% for ALCL-ALK$^-$. The 5-year OS of ALCL-ALK$^+$ however gets poorer in patients with advanced age and more advanced disease stage at presentation (see Table 89.7). BIA-ALCL displays a good prognosis if properly managed, with a 5-year OS rate of 89%.

Hepatosplenic T-Cell Lymphoma

HSTCL is an aggressive subtype of extranodal lymphoma, accounting for less than 1% of all non-Hodgkin lymphomas and less than 5% of all PTCL. A strong association with immunosuppressive treatments, such as those related with solid organ transplantation, as well as with some immune-compromised states, as it happens with pregnancy, inflammatory bowel disease, and other systemic autoimmune disorders, has been noted.[30]

Morphology and Pathobiology

HSTCL results from a proliferation of non-activated cytotoxic T cells, usually monomorphic and medium-sized, that exhibit a unique sinusoidal pattern of infiltration of the splenic red pulp, liver, and bone marrow. For this reason, diagnosis is usually confirmed on liver and bone marrow biopsy, and more rarely upon splenectomy. Neoplastic cells generally express CD2, CD3, CD7, CD16, and CD56, and lack

CD4, CD5, CD8, and CD57. Positivity for TIA-1 and granzyme-M is usually documented, but cells tend to be negative for perforin and granzyme-B. The majority (80%) of cases express the γ/δ dimer of the TCR (for this reason, the disease was previously known as hepatosplenic γ/δ T-cell lymphoma, a term now abandoned), but importantly the remaining 20% of cases express an α/β dimer.

Given the rarity of HSTCL, precise mechanisms underlying pathogenesis and disease evolution remain unclear. The most frequent known genetic abnormalities in HSTCL are isochromosome 7q and trisomy 8 but the role of somatic mutations and other genomic alterations in HSTCL has yet to be defined. Mutations in genes like *SETD2*, *INO80*, *STAT5B*, *SMARCA2*, *TET3*, and *PIK3CD* are frequently encountered. Importantly, it has been demonstrated that disruptions of *SETD2* mediate the increased cellular proliferation rate in HSTCL. On the other hand, mutations seen in other T-cell lymphomas and involving genes like *RHOA*, *CD28*, and *CCR4* are characteristically absent or occur at much lower frequency.[31]

Clinical Manifestations

HSTCL demonstrates a predilection for young males. Median age at presentation is 34 years, although epidemiology data are rather scarce. Most patients present with B-symptoms and organomegaly. Massive splenomegaly may be encountered in nearly 80% of cases; nodal involvement is not a characteristic feature, being reported in less than 25% of the cases. Hepatic involvement is the rule, but despite parenchymal infiltration elevated transaminases may only be seen in 50% of cases. Pancytopenia is common, as the bone marrow is often infiltrated. Peripheral blood lymphocytosis is uncommon and when it occurs it may mimic acute leukemia.

Prognosis

The present treatments are largely unsatisfactory, and this disease displays a severe prognosis, with a 5-year OS of 7% and progression-free survival (PFS) of 0%. Prolonged survival intervals have been anecdotally reported after an induction with alemtuzumab or cladribine or after allogeneic stem cell transplantation.

Primary Intestinal T-Cell Lymphomas

Primary intestinal T-cell lymphomas are neoplasms with an aggressive behavior that comprise approximately 20% of all intestinal lymphomas and less than 10% of all PTCL. EATL and MEITL are regarded as the most common entities and together they encompass more than 90% of all cases. Since EATL and MEITL have overlapping clinical and pathologic features, they were considered disease variants in the prior WHO classification and termed EATL types I and II, respectively. Biomolecular studies performed over the last decade have revealed biological differences that required their distinct categorization in the revised 2017 edition of the WHO classification. Both entities are described in this paragraph, but their features are presented separately.

Enteropathy-Associated T-cell lymphoma

EATL is a neoplasm derived from intraepithelial lymphocytes that develops in individuals with celiac disease, a common immune-mediated gluten-sensitive enteropathy with an incidence of nearly 1% in Western populations. This lymphoma accounts for slightly less than 5% of all gastrointestinal lymphomas and 5% of PTCL, but it is acknowledged as the most common primary intestinal T-cell lymphoma in Western countries, accounting for 66% to 80% of all cases, with a median age at onset of 64 years.

EATL is more frequently observed in Europe and the United States where the celiac risk alleles HLA DQA1*0501 and DQB1*0201 are more common, compared to Eastern regions. Homozygosity for HLA-DQ2.5 (encoded by HLA DQA1*0501 and DQB1*0201), poor adherence to a gluten-free diet, and older age are all risk factors for the development of this disease.[32]

Morphology and Pathobiology

The histopathologic features of EATL are highly variable, either among different patients or within a single case. The neoplastic lymphocytes morphologically vary between highly polymorphic elements to a more monomorphic appearance, sometimes resembling immunoblastic elements. In some cases, a mixed inflammatory infiltrate composed of histiocytes, eosinophils, and plasma cells may obscure the malignant cells. The histiocytic granulomatous aggregates may lead to the mistaken impression of Crohn disease. The neoplastic cells frequently spread within the epithelial compartment thus migrating adjacently to or distantly from the initial tumor mass. Portions of small intestine away from the tumor mass frequently show typical histopathologic features of celiac disease; importantly, however, mucosal changes are more prominent proximally and tend to improve distally.

EATL typically expresses CD103, CD2, cytoplasmic CD3, CD7, TIA-1, perforin, and granzyme-B, and lack CD4, CD5, and CD56 expression. Most cases lack surface CD3 and TCR. The Ki-67 proliferation index is generally higher than 50%.

Virtually all EATL cases have clonal TCR rearrangements, mainly of β and γ chain genes, with an association to HLA DQA1*0501 and DQB1*0201, as said. Genome-wide copy number analyses have revealed recurrent gains of chromosomes 9q, 7q, 1q, 5q, and losses of 16q, 8p, 13q, 9p, but a clear identification of the altered genes remains largely unknown. Recurrent genetic mutations have been detected in members of the JAK-STAT pathway (*JAK1, JAK3, STAT3 STAT5B, SOCS1*), MAPK pathway (*BRAF*, *KRAS*, *NRAS*), and epigenetic modifiers (*TET2*, *SETD2, YLPM1*); mutations in DNA damage response and repair and tumor suppressor genes (*TP53*, *BRIP1*, *TERT*, *BCL11b*, *DAPK3*, *PRDM1*) have also been reported.[33]

Clinical Manifestations

EATL may be associated with abdominal discomfort and pain at onset, along with fatigue, anorexia, diarrhea, nausea and vomiting, and possibly B-symptoms, especially weight loss. Symptoms may be present for weeks to years prior to the diagnosis of EATL or may arise acutely in individuals without known celiac disease. Likewise, reappearance of malabsorption in a patient with a history of celiac disease favorably responding to a gluten-free diet or, alternatively, the sudden onset of gluten-insensitive severe malabsorption in an otherwise healthy individual can be key symptoms of disease at its onset. More than half of the patients with EATL (58%) have no prior diagnosis of celiac disease and in these cases celiac disease is diagnosed either concurrently with EATL or afterward.

Nearly half of the patients present with an acute abdomen secondary to intestinal perforation and hemorrhage, because of disease penetration into the intestinal wall. The jejunum is the mostly affected site, although any segment can be involved. When multiple segments of the small intestine have been involved, it is likely that the disease has disseminated to nearby and distant organs (mesenteric nodes, liver, spleen, lungs, and bone marrow).

Refractory Celiac Disease

In some celiac disease patients, development of EATL is preceded by a precursor disease state known as refractory celiac disease (RCD): this is defined as the persistence—or recurrence—of severe gastrointestinal symptoms and villous atrophy despite adherence to a gluten-free diet for at least 12 months, after excluding any secondary etiologies for the symptoms. RCD has been categorized into two subtypes (RCD-I and RCD-II): RCD-I represents a polyclonal expansion of intraepithelial lymphocytes that display a normal immunophenotype, whereas RCD-II (also known as intraepithelial T-cell lymphoma or *cryptic* EATL), is a clonal proliferation of immunophenotypically abnormal intraepithelial lymphocytes. Both RCD-I and RCD-II patients experience recurrent or persistent episodes of malabsorption, but the severity of malnutrition in RCD-II is usually more profound than in RCD-I. Also, the risk of developing EATL is different between the two subpopulations, being 3% to 14% within 5 years in patients with RCD-I compared to nearly 50% in RCD-II.

Prognosis

The clinical course of this disease is very unfavorable and roughly 20% of patients are alive at 5 years. Surgical resection of the affected intestinal tract may offer longer remission rates only in case of a single focal lesion. In most instances, however, the disease involves multiple segments of the gastrointestinal tract or has disseminated to lymph nodes or distant organs.

Monomorphic Epitheliotropic Intestinal T-Cell Lymphoma

MEITL is the second most common primary intestinal T-cell lymphoma. It occurs in older adults, with a median age of 61 years and shows male predominance (male-to-female ratio of 2:1). In contrast to EATL, there is no definitive association with celiac disease.

Morphology and Pathobiology

The neoplastic infiltrate is composed of a monotonous (thus the term *monomorphic*) population of small- to medium-sized T-lymphocytes lacking neoplastic features but characterized by the presence of a rim of clear or pale pink cytoplasm. At the periphery of the tumor, the neoplastic cells often demonstrate epitheliotropism. The immunophenotype overlaps with one of the normal intraepithelial lymphocytes (CD103$^+$, CD3$^+$, and CD8$^+$), although CD56 is commonly expressed, along with cytotoxic markers (TIA-1 and granzyme-B). MEITL expresses TCR γ and β chains in 23% to 61% and 16% to 46% of the cases, respectively; 6% to 33% of the cases are TCR silent and 16% are positive for both TCR γ and β chains. Megakaryocyte-associated tyrosine kinase (MATK) is expressed almost constantly (87% of the cases), being particularly helpful in distinguishing MEITL from EATL.[34]

Similar to EATL, gains at 9q (48% to 70%) and losses at 16q (23% to 56%) represent the most common copy number alterations; gains of chromosome 8q24 (with the involvement of the *MYC* locus) are also frequent, but *MYC* rearrangements are rare. The most common mutations occur in members of the JAK-STAT (76% to 83%) and MAPK (32% to 56%) pathway and deletions or mutations that inactivate *SETD2* are observed in the majority of MEITL (up to 80% of the cases). Finally, *SYK* and *NCAM1* (CD56) are more frequently overexpressed in MEITL compared to EATL.

Clinical Manifestations

Approximately half of MEITL patients are asymptomatic, whereas a few patients complain of non-specific gastrointestinal symptoms, like abdominal pain, weight loss, nausea or vomiting, and diarrhea. In a significant proportion of cases, however, the disease has an abrupt onset with an acute abdomen due to intestinal perforation. The disease is usually multifocal within the intestinal tract, with jejunum and ileum being the mostly affected sites; also, the colon and the stomach may be affected (10% to 28% and 5% of the cases, respectively). Extraintestinal dissemination to mesenteric lymph nodes or pelvic organs is common, whereas extra-abdominal diffusion is rare.

Extranodal NK/T-Cell Lymphomas

ENKL is a rare neoplasm occurring with higher prevalence among Asians, Mexicans, and South Americans of Native American ethnic origin. It accounts for approximately 6% of all non-Hodgkin lymphomas in these ethnic groups (20% to 40% of all PTCL), as opposed to nearly 1.5% in all other populations (up to 4% to 5% of all PTCL). This neoplasm affects adults almost exclusively, with a median age at presentation of 49 to 53 years and a male-to-female ratio ranging from 2:1 to 3:1. The nasal cavity is the most common site of involvement and it was the prototypic site when this disease was initially characterized; for this reason, the neoplasm is generally termed *nasal type*, although extranasal localizations—even with lack of nasal/paranasal involvement—do exist.

EBV seems to play an important role in lymphomagenesis, as it is invariably detected in nasal ENKL cases, irrespective of patients' origins, and in the great majority of lymphomas presenting outside the nasal cavity. Iatrogenic immunosuppression may facilitate the development of this neoplasm, e.g., in renal transplant recipients.

Morphology and Pathobiology

The affected tissue appears diffusely infiltrated by packed lymphoma cells. Infiltrating cells are small-to-medium in size, sometimes larger, with irregularly folded nuclei and a variable amount of cytoplasm. Necrosis is common. The presence of tumor cells is accentuated around blood vessels (*angiocentric growth*), with their walls being infiltrated and destructed and their lumen frequently thrombosed. The immunophenotype of neoplastic cells is prototypically CD2$^+$, CD3$^-$, CD56$^+$; CD43 and CD45RO are commonly positive; the expression of CD7 is variable. Other T-cell-associated antigens, such as CD4, CD5, CD8, and α/β-γ/δ TCR are negative (TCR is in germline configuration in virtually all cases). Cytotoxic molecules like perforin, granzyme-B, and TIA-1 are usually positive. CD30 is positive in about one half of cases; its staining is focal and not as intense as in other PTCL. The proliferative fraction, according to Ki-67, is usually higher than 50%; the higher the rate, the worse the prognosis, especially with nasal presentation.

Overexpression of TP53 is found in 45% to 86% of the cases, along with *TP53* gene mutations in a quarter to two-thirds of the cases. Mutations of β-catenin, *KRAS*, and *c-KIT* genes can be detected in 6% to 20% of cases, although their biologic role is unclear. Demonstration of killer cell immunoglobulin-like receptor (KIR) repertoire restriction along with germline TCR genes is useful to support the monoclonal nature of the process and to confirm its NK-cell origin.

Clinical Manifestations

Nasal ENKL arises in the nasal cavity, nasopharynx, or upper aerodigestive tract, causing both obstructive symptoms and destructive and ulcerative lesions. The disease shows a tendency to spread to nearby tissues and structures, such as the orbits, the paranasal sinuses, the oral cavity, and the palate, usually determining bone erosions; it may also extend to the oropharynx. Extranasal sites are far less involved than nasal cavity and paranasal spaces; the skin is the most frequently affected site, along with the gastrointestinal tract, the testis, and the lung. Eye and facial soft tissues can also be involved, as it happens during the dissemination of primary nasal type disease.

Early-stage disease (I–II) characterizes patients with nasal involvement; clinical symptoms are mostly related to facial destruction and bone marrow involvement is exceedingly rare. On the contrary, patients with extranasal disease frequently display advanced stage (III–IV) at presentation and often complain of systemic symptoms. Skin nodule ulceration, bowel obstruction, or perforation and testicular masses characterize the extranasal spread of this lymphoma.

Prognosis

High response rates and favorable long-term survival rates can be obtained in patients with localized disease with radiotherapy or chemotherapy + radiotherapy approaches, as discussed below, and 5-year OS rates range from 40% to 78%. Relapse is common, however. Extranodal or advanced disease is much more aggressive and difficult to treat. Long-term survival rates for patients with advanced disease are dismal, and median OS is only 4.3 months.

Subcutaneous Panniculitis-Like T-Cell Lymphoma

SPLTCL is a mature lymphoma of cytotoxic α/β T-cell derivation that involves the subcutaneous fat similarly to panniculitis. It is a rare disease involving predominantly young individuals (both young adults and children), with a median age at onset of 35 years and no clear sex predilection. This is acknowledged as an extranodal T-cell lymphoma, but more correctly included in the classification of CTCL.

Morphology and Pathobiology

Atypical lymphoid T cells of variable size admixed to benign histiocytes infiltrate the subcutaneous tissue, sparing the overlying dermis and epidermis. Neoplastic lymphocytes rim adipose spaces, and fat necrosis is frequently encountered. Vascular invasion is a common feature. Tumor cells characteristically express CD3 and CD8 but lack CD4. Perforin, granzyme-B, and TIA-1 are present. Positive stain for βF1, an antibody that identifies the α/β dimer of the TCR, is characteristic.

Clinical Manifestations

Solitary nodules or plaques are the hallmark of the disease, usually involving the lower extremities, but sometimes spread to both arms and the trunk. Nodules display variable dimensions; they have an indurated appearance and do not ulcerate. Systemic symptoms, like fever and weight loss, may also be present.[35]

Prognosis

The 5-year disease-specific survival is 80%, as the disease rarely disseminates to lymph nodes and distant organs; recurrences may be observed over periods of several years, but they tend to remain confined to subcutaneous tissue. Very rare cases associated with hemophagocytic syndrome display an aggressive behavior and a poor outcome.

First-Line Therapy

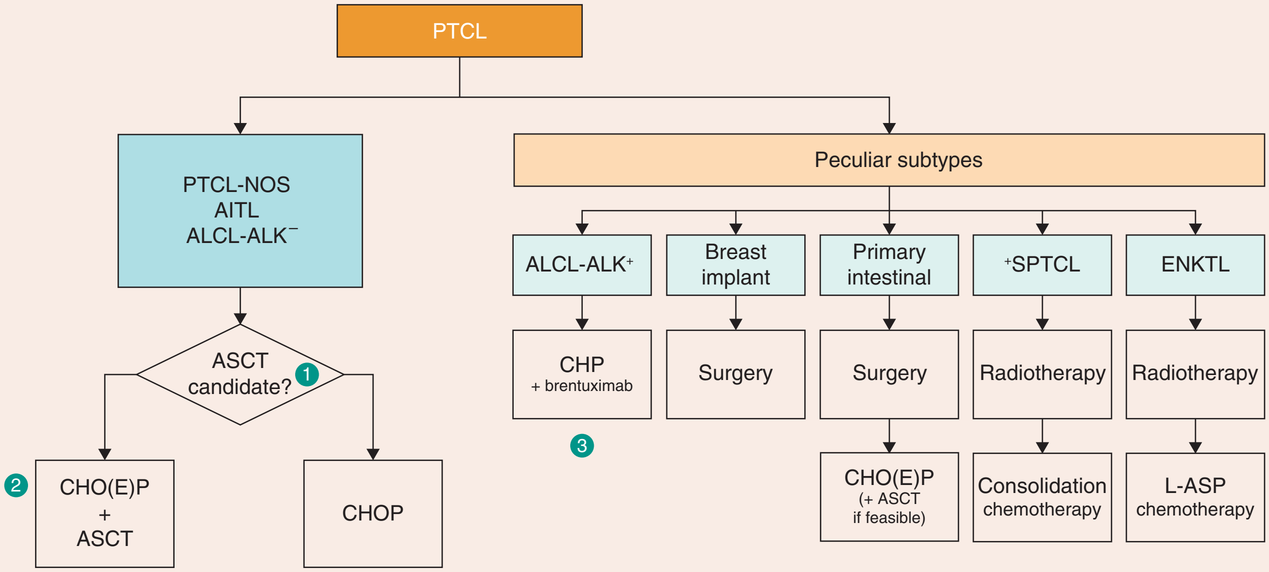
The main goal of first-line treatment should be the achievement of at least a partial remission, in order to apply a consolidative autologous stem cell transplantation (ASCT), where appropriate (described later in the chapter), and to enhance the opportunity of a good control of the disease in the long term.

The treatment strategies most widely adopted in aggressive PTCL are the same applied in aggressive B-cell lymphomas; however, as PTCL are biologically and clinically different from the B-cell counterparts, a significant prognostic gap exists between lymphoma of B- and T-cell origin when the same (or at least very similar) approaches are applied.

Data regarding treatment results can be difficult to analyze given that most of—if not all—the older studies report on all entities of PTCL treated together as a single entity. For this reason, treatment modalities for the initial treatment of nodal aggressive PTCL are presented together. The growing knowledge about the heterogeneity of PTCL has in part led to separate certain entities from others as far as treatment approaches are concerned. This is particularly true for extranodal PTCL, in which surgery or radiotherapy may play a major role, and for ENKL, given the peculiar sensitivity of this disease to selected classes of cytostatic agents. The treatment of specific disease subtypes is discussed below and in the box on Frontline Management of PTCL.

FRONTLINE MANAGEMENT OF PTCL

- Systemic chemotherapy is the mainstay of frontline treatment in all nodal forms. Anthracycline-containing regimens (like CHOP) are generally acknowledged as the gold standard. Etoposide may be added (CHOEP regimen).
- Autologous stem cell transplantation (ASCT) is generally regarded as the most suitable consolidation treatment, and for this reason it is given frontline, provided the patient is eligible (review patient's comorbidities, disease status, performance status, age).
- Some peculiar PTCL subtypes may require a different treatment because of: (a) lower risk of disease progression or relapse over time (ALCL-ALK$^+$); (b) curability with loco-regional procedures (e.g., surgery in breast implant-associated ALCL; radiotherapy in SPTCL); c) clear extranodal presentation (e.g., primary intestinal T-cell lymphomas).



Controversial Points

1. Can new drugs be added to the standard CHOP backbone (e.g., brentuximab vedotin in CD30$^+$ disease, lenalidomide in AITL)?
2. Can frontline ASCT be avoided in patients achieving a complete remission?
3. Do we need ASCT consolidation in ALCL-ALK$^+$ patients with higher-risk disease (e.g., IPI ≥ 2)?

ASCT is regarded as a key step in the consolidation of an initial response. However, its role is still debated, as we lack evidence of its benefit in patients in first CR. Experiences with ASCT in PTCL is discussed later.

Induction Regimens

Anthracycline-based regimens are the mainstay of induction treatment of PTCL patients, as demonstrated in several reported experiences in which the CHOP combination was adopted in a range of patients variable from 60% to 85%. The overall response rates (ORR) ranged from 70% to 80% for ALCL-ALK$^-$ patients, with CR rates in up to 50% of the cases. On the contrary, ALCL-ALK$^+$ patients responded to first-line CHOP in up to 90% of cases. Nearly 40% of patients with ALCL-ALK$^+$ disease and roughly 60% of those with ALCL-ALK$^-$ disease however failed to maintain their response over time with induction only. The role of anthracyclines as part of the induction schedule is much more debated in AITL and PTCL-NOS. On the one hand, it should be noted that according to the ITCLP the CR rate observed in patients receiving an anthracycline-based induction was 61% for AITL patients and 56% for PTCL-NOS patients, however with no significant survival advantage for those receiving anthracyclines when compared to patients treated with anthracycline-free schedules. On the other, different data sets indicate that anthracycline-containing regimens can improve OS and PFS in all patients affected by PTCL, particularly in those with AITL and PTCL-NOS subtypes, and that the benefit is reinforced when ASCT is applied as first-line consolidation.[36–40]

A retrospective analysis of German T-cell lymphoma trials suggested that the addition of etoposide to CHOP can be more effective than CHOP alone, at least in PTCL-NOS and ALCL patients; the CHOEP regimen, given either every 14 or 21 days, improved response and event-free survival (EFS) rates in young patients with normal LDH levels (3-year EFS was 70.5% after CHOEP and 51.0% after CHOP), although 3-year OS did not significantly differ between the two groups. In addition, CHOEP failed to enhance clinical outcomes in patients older than 60 years, for whom CHOP should remain the standard first-line approach.[41]

Combination of New Drugs With Standard Chemotherapy

Given that CHOP is regarded as the reference regimen for the induction treatment of patients with PTCL, it has been used as a backbone for new first-line combination regimens which incorporate drugs that have demonstrated their efficacy when used as single agents in relapsed or refractory patients (refer to "Treatment of relapsed and refractory disease" paragraph for a more detailed description of these agents.) First-line combination treatments are intended to enhance CR rates, to allow a higher proportion of patients to undergo ASCT in remission and to prolong survival (Table 89.8).

Phase 1/2 trials combining pralatrexate, romidepsin, belinostat, and alemtuzumab with CHOP and CHOP-like regimens have shown the feasibility of the proposed combination. Nevertheless, published studies are relatively small and sometimes displayed a high incidence of toxic events. Randomized trials exploring the combination of alemtuzumab with CHOP have been completed but have failed to show the superiority of the combination regimen, both in terms of disease control and as far as OS and PFS are concerned. The combination of romidepsin and CHOP has not demonstrated any superiority over standard CHOP.

The only clearly positive study was ECHELON-2, a large double-blind multicenter randomized phase 3 trial. This trial tested the combination of brentuximab vedotin (BV) plus cyclophosphamide, doxorubicin, and prednisone (BV-CHP regimen) versus standard CHOP in previously untreated subjects with CD30-expressing PTCL (at least 10% of the cells). The experimental arm did not include vincristine in order to minimize the incidence of peripheral neuropathy, given the concomitant administration of BV. Consolidative transplantation, in case of response, was not mandatory, but its application was at discretion of treating physicians. Each arm enrolled 226 patients, with a median age of 58 years and with an advanced stage (Ann Arbor III-IV) in at least 80% of cases. Patients with systemic ALCL represented the majority of patients (72% in the BV+CHP arm and 68% in the CHOP arm), followed by PTCL-NOS (13% and 19%, respectively), AITL (13% and 11%, respectively), and rarer entities. An overall response was seen in 83% of patients in the experimental arm and in 72% of those treated with CHOP, with CR in 68% and 56% of cases, respectively. The 3-year PFS was 57% for the BV+CHP arm and 44% for the CHOP arm (Fig. 89.6); importantly, this difference remained statistically significant even when patients were censored for PFS immediately before they received stem cell transplantation or radiation therapy, thus indicating that the combination of BV and chemotherapy retains its effectiveness regardless of any subsequent consolidation.[42]

Based on these results, in November 2018 the Food and Drug Administration (FDA) approved BV for the treatment of adult patients with previously untreated systemic anaplastic large cell lymphoma or other CD30$^+$ PTCL in combination with CHP. However, most of the patients in the study had ALCL and the benefit for the BV-CHP

TABLE 89.8 **CHOP Combinations With New Agents in the Frontline Treatment of Peripheral T-Cell Lymphomas**

Combination	Phase	Randomization	Pts.	ORR, %	CR, %	PFS, %	OS, %
Pralatrexate + CHOP	1	None	31	89	67	—	—
Belinostat + CHOP	1	None	23	89	72	—	—

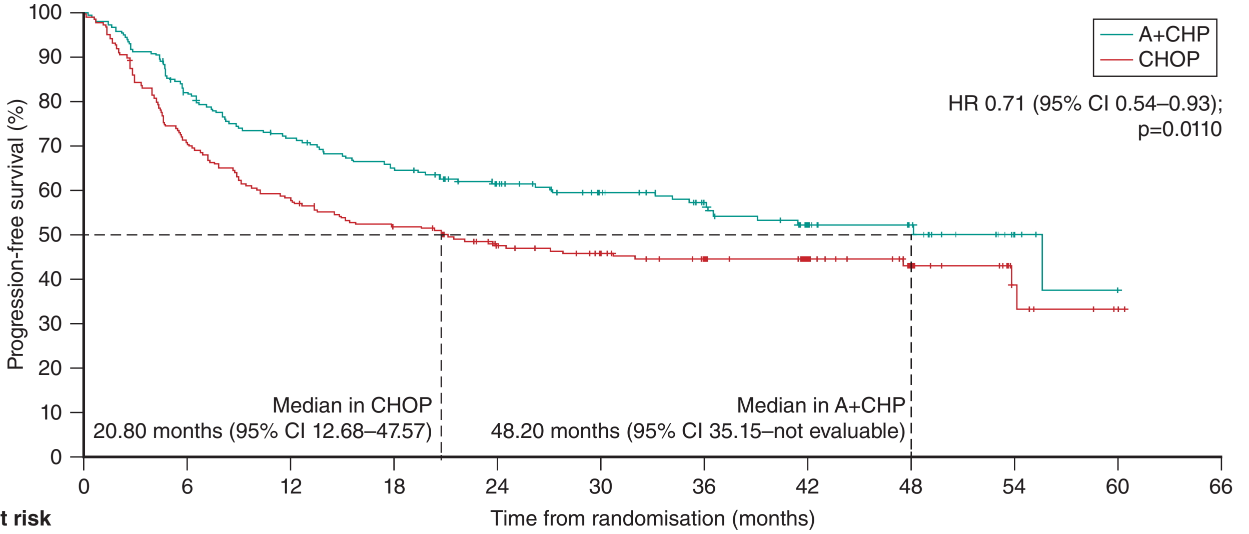
		CHOP	58		43	29 (3 years)	56 (3 years)



Number at risk (number censored)

	0	6	12	18	24	30	36	42	48	54	60	66
A+CHP	226 (0)	175 (39)	149 (61)	134 (75)	108 (82)	81 (85)	64 (88)	38 (93)	24 (93)	9 (94)	3 (95)	0 (95)
CHOP	226 (0)	157 (65)	129 (93)	112 (107)	87 (116)	75 (119)	63 (121)	44 (121)	26 (122)	7 (123)	2 (124)	0 (124)

Figure 89.6 PROGRESSION-FREE SURVIVAL IN PATIENTS TREATED IN THE BV$^+$CHP ARM COMPARED TO THOSE IN THE CHOP ARM. *(Reprinted with permission from Elsevier, Horwitz S, et al. Brentuximab vedotin with chemotherapy for CD30-positive peripheral T-cell lymphoma (ECHELON-2): a global, double-blind, randomized, phase 3 trial. Lancet. 2019; 393: 229–240.)*

regimen was not statistically significant in non-ALCL subtypes. Therefore, the evidence is not as strong as with ALCL to recommend BV-CHP in the frontline treatment of CD30$^+$ non-ALCL PTCL.

Frontline Autologous Stem Cell Transplantation

Patients responding to first-line chemotherapy treatment generally display a short duration of remission and a high risk of relapse; for this reason, a frontline consolidation with ASCT has been considered a valid therapeutic opportunity for patients achieving a response to induction. This strategy seems to be particularly important for those with intermediate to high IPI score, while it is not indicated for ALCL-ALK$^+$. This is mainly because ALCL-ALK$^+$ cases have not been enrolled in prospective clinical trials evaluating the role of upfront ASCT, mainly because of their overall better prognosis compared to the remaining nodal entities.

The first multicenter prospective trial aimed at establishing the benefit of frontline ASCT in PTCL patients has involved 111 patients, treated with 6 to 8 CHOP induction cycles followed by mobilizing chemotherapy and total-body-irradiation + cyclophosphamide myeloablative conditioning, with the rescue of autologous stem cells. Overall, 68% could successfully undergo ASCT, while failure to do so was mainly related to early disease progression. Patients obtained a CR in 59% of the cases after myeloablative conditioning, with 5-year OS, disease-free survival (DFS), and PFS rates of 44%, 54%, and 39%, respectively, for the entire intention-to-treat population.[43]

The Nordic Lymphoma Group applied a CHOEP induction strategy (given every 14 days), although omitting etoposide in patients over 60 years, in 160 PTCL patients. The fifth or sixth cycle was used as a mobilizing therapy, while the upfront ASCT was conditioned by carmustine, etoposide, cytarabine, and melphalan (or high-dose cyclophosphamide). The reported CR rate was 51%; the 5-year OS and PFS were 51% and 44% for the entire patient population, respectively.[44]

These trials indicate that ASCT consolidation is able to offer a chance of long-term survival in PTCL patients. Nevertheless, it should be noted that a substantial proportion of patients (16% to 41%) had evidence of disease progression during induction or immediately before transplantation, thus precluding an effective consolidation in a relevant proportion of cases.

A systematic review and meta-analysis of 27 publications covering 1368 patients reported a PFS rate of 33% for the prospective studies analyzed, with an OS of 54% and a transplant-related mortality (TRM) of 2%. It is worthwhile to note that these studies are inherently biased by the selection of better outcome patients (i.e., only patients with good quality responses are candidates for ASCT), and that about one-third of the enrolled patients have failed to receive the planned ASCT either because they did not achieve a remission or due to early progression.[45]

Results from the Comprehensive Oncology Measure in Peripheral T-cell Lymphoma Treatment (COMPLETE) study have recently been reported. This observational study identified 119 patients with nodal PTCL in first CR; 36 of them received ASCT whereas 83 did not. In multivariate analyses, ASCT was independently associated with improved OS (49); in particular, ASCT was associated with superior survival for patients with advanced-stage disease or intermediate-to-high IPI. In terms of PTCL histology, ASCT significantly improved OS and PFS for patients with AITL but not for patients with other PTCL subtypes.[46]

This issue has been recently analyzed by some registry studies, which collectively failed to show an advantage for ASCT when the analysis focused on patients in CR after induction. In a French study of over 500 patients, 57% of responders had the same outcome regardless of whether they received ASCT or not, with a 5-year OS and PFS of 60% and 45%, respectively, for both groups.[47]

In conclusion, no randomized trials have specifically clarified whether upfront ASCT should be regarded superior to conventional chemotherapy only or, more specifically, if patients in CR after induction strictly require a high-dose chemotherapy consolidation. However, upfront consolidation with ASCT is still recommended by current guidelines for patients with chemo-sensitive PTCL-NOS, AITL, and other rare subtypes when in first CR after induction (see box on Frontline Management of PTCL).

Treatment of Specific Disease Subtypes

Much more disappointing results have been achieved with standard chemotherapy in patients affected by extranodal disease subtypes, like EATL, HSTCL, SPTCL, and ENKL, which nowadays still represent a clearly unmet medical need. Alternative treatment strategies, other than standard chemotherapy, are urgently required.

Low-risk ALCL-ALK$^+$ (IPI 0 to 1)

Given the overall better prognosis of this disease entity, ASCT is not generally considered as part of initial therapy in this category of patients. Those with low IPI score, and more in general those whose IPI score is lower than 3, may take advantage of an anthracycline-containing induction (either CHOP or CHOEP, as discussed above), without the need of consolidation with ASCT. Of note, the most relevant trials of ASCT in PTCL have excluded ALCL-ALK$^+$ patients, therefore no definitive conclusions may be drawn for this category of patients on the role of ASCT.[39,40]

BIA-ALCL

Complete surgical excision, with removal of the implant, total capsulectomy, and complete avulsion of any associated mass with negative margins upon pathological evaluation, is recommended in any patients either presenting with effusion or tumor masses. Systemic chemotherapy alone is insufficient unless applied after surgical resection. At least 30% of patients undergoing chemotherapy showed unsatisfactory responses or progressed in a published series of 87 patients with BIA-ALCL, whereas only 4% of patients had recurrence or progression when treated by complete resection of the implant, tumor tissue, and fibrous capsule. Better OS and PFS rates were described for patients undergoing complete surgical excision in comparison to those who received chemotherapy, radiotherapy, or a limited/partial surgical approach (partial capsulectomy, implant removal or replacement, excisional biopsy of capsule or tumor mass). Multi-agent chemotherapy is justified in cases with a tumor mass presentation at onset rather than with effusion only, as these patients are thought to display a more aggressive clinical behavior. Chemotherapy is also required when disease disseminates to nearby and distant nodes; however, any systemic approach needs to be preceded by a radical surgical resection.[48,49]

EATL and MEITL

Patients with EATL and MEITL display one of the poorest prognoses among all patients with PTCL, with a 5-year OS and PFS of only 20% and 4%, respectively, even in case of favorable IPI score. An initial surgical approach is rather common in EATL and MEITL patients, as many of them show acute abdominal symptoms (bowel perforation, hemorrhage, obstruction) requiring prompt intervention. An intensified induction with an ifosfamide-containing regimen and methotrexate, followed by ASCT has demonstrated better outcomes in terms of OS and PFS (60% and 50% at 5 years, respectively) if compared with historical controls receiving standard anthracycline-containing inductions. Nevertheless, overall toxicity is not negligible, and most patients are unable to tolerate this aggressive approach or fail to proceed to ASCT consolidation because of poor performance status after surgery, rapid disease progression, or clinical decay.[50,51]

SPTCL

Radiation therapy (20 to 30 Gy), possibly preceded by reductive surgery, should be recommended in patients with localized lesions. Multiple, non-contiguous lesions may be treated with pulse steroids (prednisone or equivalents), at the dose of 0.6 to 0.7 mg/kg/day × 10 days/month. Systemic chemotherapy with gemcitabine, or multiagent chemotherapy (CHOP, CHOP-like) is advisable in case of systemic dissemination or progressive disease.

ENKL

Management strictly depends on stage at presentation and local *versus* distant disease spread. Patients with localized ENKL, which means a disease that involves the nose and the nasal sinuses, may benefit of external radiation therapy (at a dose of at least 50 Gy), which is sometimes the only required treatment. In a cooperative study from Japan, concurrent systemic chemotherapy has also been administered in nearly three-quarters of patients, the dexamethasone, etoposide, ifosfamide, and carboplatin (DeVIC) regimen being the most widely used. Patients with primary disease localization other than nose and nasal sinuses rarely show localized disease and require systemic multiagent approaches. ENKL has proved to be particularly sensitive to L-asparaginase, which has been incorporated in several induction schemes, like SMILE (dexamethasone, methotrexate, ifosfamide, L-asparaginase, etoposide), which produced higher response rates (79% of ORR, with 45% of CR) if compared to standard anthracycline-containing inductions.[52] Toxicity is severe, however, and this regimen should be applied with a careful supportive treatment. An asparaginase-containing regimen, the GELOX (gemcitabine, L-asparaginase, oxaliplatin), has also been applied with concomitant radiotherapy in localized-stage ENKL, yielding an ORR of 96%, with at least 74% of patients achieving a CR.[53]

Relapsed and Refractory Disease

Survival outcomes for patients with PTCL who relapse or progress after first-line treatment are very poor. In a series of 153 patients with relapsed/refractory PTCL diagnosed between 1976 and 2010 from the British Columbia Cancer Agency, it was shown that the median PFS and OS after first recurrence or disease progression were only 3.1 and 5.5 months, respectively, without stem cell transplant. Those receiving systemic chemotherapy after progression or relapse did not have significantly improved survival compared to those who did not. Only a small number of patients survived a relatively long period without transplant with 3-year OS of 18%. There was no significant difference in PFS and OS after first recurrence or disease progression by PTCL subtypes. Similar results have been reported by other research groups. Interestingly, however, patients with ALCL seem to display better OS outcomes with first salvage treatments if compared to AITL and PTCL-NOS, with 47.3 - and 10.8-months median OS for ALCL-ALK$^+$ and ALCL-ALK$^-$, respectively.[39,54]

These results clearly indicate that PTCL patients failing an initial treatment are generally hard to be saved with conventional chemotherapy, thus representing a clear unmet medical need. New agents targeting specific molecular hallmarks of these disease entities may have a rationale in the treatment of relapsed and refractory patients. Licensed agents and off-label compounds are discussed in detail in the next paragraphs (Table 89.9).

TABLE 89.9 **Selected Experiences With Food and Drug Administration (FDA)-Approved Single Agents and Off-Label Compounds in Relapsed and Refractory Peripheral T-Cell Lymphomas Patients**

Treatment	AITL		PTCL-NOS		ALCL	
	ORR, %	CR, %	ORR, %	CR, %	ORR, %	CR, %
Pralatrexate[a]	8	—	32	—	35	—
Romidepsin[a]	30	19	29	14	24	19
Belinostat[a]	46	—	23	—	15	—
Brentuximab vedotin[b]	54	38	33	14	86	57
Lenalidomide[c]	33	11	43	14	10	0
Mogamulizumab[c]	50	25	19	6	100	100*

ORR, overall response rate; *CR*, rate of complete responses (if available).

[a] The drug has received a Food and Drug Administration approval in patients with relapsed and refractory peripheral T-cell lymphoma.

[b] The drug has received a Food and Drug Administration approval in patients with CD30$^+$ relapsed or refractory anaplastic large cell lymphoma.

[c] This compound is used off-label for the treatment of relapsed and refractory PTCL.

*Response is established on 1 ALK-negative patient.

Licensed Agents

As of the writing of this chapter, 5 compounds have been approved by the FDA for their specific use as single agents in the setting of patients with relapsed or refractory PTCL: pralatrexate, a novel antifolate agent; romidepsin and belinostat, both histone deacetylase (HDAC) inhibitors; BV, an anti-CD30 drug-conjugated monoclonal antibody; and mogamulizumab, an anti-CC chemokine receptor 4 (CCR4) monoclonal antibody. Although available in the United States, the European approval of both pralatrexate and romidepsin has been rejected due to a lack of evident clinical benefit; belinostat is not licensed in Europe, but it has been granted orphan designation status by the European Medicines Agency. In fact, their approval by the FDA was based on response rates alone and not on a documented increase in OS. BV has granted approval for the treatment of relapsed or refractory systemic ALCL and now it is moving to frontline PTCL treatment according to the results of the ECHELON-2 trial (see above). Mogamulizumab is now approved for ATLL in Japan and in pretreated MF and SS patients (see section on CTCL).

Pralatrexate

Pralatrexate is an aminopterin derivative administered intravenously with high affinity for the reduced folate carrier-1 and for folypolyglutamate synthase. This causes the retention of the drug in the cytoplasm and a potent inhibition of dihydrofolate reductase, which ends up with blocking the reduction of dihydrofolate to tetrahydrofolate. Given that tetrahydrofolate works as a cofactor for the metabolism of some amino acids (such as methionine, serine, and glycine) and for the synthesis of pyrimidines and purines, pralatrexate ultimately causes a depletion of thymidine monophosphate and other nucleotides, thus determining cell-cycle arrest and apoptosis.

The phase 2 registration trial was PROPEL, a single-arm study that involved 115 patients with relapsed or refractory PTCL, 111 of whom received at least 1 dose. The majority of patients had PTCL-NOS followed by systemic ALCL and AITL (53%, 15% and 12%, respectively), all heavily pretreated. Pralatrexate was administered intravenously at the dose of 30 mg/m^2/week for 6 weeks, followed by 1 week of rest, until progressive disease or unacceptable toxicity, as determined in a previous phase 1 study. The ORR was 29%, including 11% of patients with CR and 18% with partial response (PR). A quarter of patients without a response to the most recent prior treatment responded to pralatrexate, as well as 19% of those who had never achieved a response. Responses were seen across all histologies, although patients with AITL responded less well than those with PTCL-NOS or ALCL (8% vs. 32% and 35%, respectively). ORR raised to 35% among less treated patients. The median PFS for the entire population was 3.5 months, with a median OS of 14.5 months. Mucositis was the most relevant adverse event, which determined dose reductions in 23% of patients and caused withdrawal from treatment in 6% of cases.[55]

Histone Deacetylase Inhibitors

HDAC inhibitors alter the acetylation pattern of histone lysine residues. They mainly work through chromatin remodeling and restoration of normal gene expression in cancer cells, which results in cell growth inhibition, cell cycle regulation, and induction of apoptosis. However, HDAC can target substrates other than histones and may play a role in the post-translational acetylation of proteins. HDAC inhibitors therefore interfere with several other cellular mechanisms, like autophagy, cell differentiation and cell cycle progression, modulation of immune responses, and suppression of angiogenesis. Romidepsin and belinostat are the two HDAC inhibitors tested in PTCL patients that received FDA registration for their use as single agents in relapsed and refractory PTCL patients.

Romidepsin is a cyclic tetrapeptide (depsipeptide) that selectively inhibits class 1 HDAC after its interaction with the zinc atom in the binding pocket of the enzyme. It has been shown that romidepsin is capable of downregulating the pro-survival NFκB, PI3K-AKT and β-catenin pathways in PTCL patients; it can also increase the production of reactive oxygen species, decrease the mitochondrial membrane potential and put malignant T cells under significant biologic stress.

The phase 2 registration study involved 130 relapsed or refractory and advanced-stage PTCL patients, among which there were 69 PTCL-NOS, 27 AITL, and 21 ALCL-ALK$^-$. The trial demonstrated an ORR of 25%, with 19% CR and with 29% of patients responding despite being refractory to their most recent prior systemic therapy. The median PFS was 4 months for the entire cohort of patients, raising to 18 months for patients in CR, and OS was 11.3 months. Adverse events were predominantly hematologic and included neutropenia, lymphopenia, thrombocytopenia, and anemia. Nausea, fatigue, vomiting, diarrhea, anorexia, and dysgeusia were among the most prevalent—albeit not severe—nonhematologic adverse events, reported in at least 20% of the patients enrolled in the trial.[56]

Belinostat is a hydroxamic acid-derived pan-HDAC inhibitor. Like other HDAC inhibitors, it regulates apoptosis and cell cycle arrest of transformed cancer cells. It is administered intravenously over 30 minutes at the fixed dose of 1000 mg/m^2 on days 1 to 5 every 21 days, as established in phase 1 escalation dose studies in patients with advanced malignancies, and treatment is maintained until unacceptable toxicity or progression.

The phase 2 registration trial (BELIEF) involved 129 patients with relapsed or refractory PTCL, more than half affected by PTCL-NOS. The ORR was 23%, most impressively in AITL patients (for whom ORR was 46%), whereas none of those affected by extranodal T-cell variants (intestinal T-cell lymphomas and HSTCL) achieved a response. Of note, meaningful responses were seen in 16% of patients refractory to their last prior systemic treatment, although patients who displayed a CR to their last prior treatment could obtain a higher ORR (48%). Median PFS was however only 1.6 months and the median OS was 7.9 months. In terms of safety, relevant adverse events were nausea, fatigue, and pyrexia; anemia, neutropenia, and thrombocytopenia were overall the most common grade 3 to 4 toxicities, although belinostat seemed apparently less myelotoxic than romidepsin.[57]

Brentuximab Vedotin

BV is an antibody-drug conjugate which enables the delivery of a cytotoxic agent directly to its malignant target, composed by an anti-CD30 antibody conjugated through a protease-cleavable linker with monomethylauristatin E (MMAE), a potent microtubule-disrupting agent. Once the antibody has bound to CD30 on the cell surface, the complex is internalized and trafficked to lysosomes, where MMAE is released by proteolytic cleavage. The cytotoxic effects of MMAE on the microtubule network cause cell cycle arrest and induce apoptotic death. It is plausible that a certain amount of MMAE is uptaken by the tumor microenvironment and subsequently released to tumor cells regardless of antibody binding. This would explain in part the efficacy of BV also in context of low (or sometimes even absent) CD30 expression.

BV is now approved in the treatment of relapsed and refractory ALCL, according to the results of the pivotal phase 2 trial. This study involved 58 systemic ALCL patients with a confirmed CD30$^+$ status by immunohistochemistry. An objective response was obtained in 86% of the cases, with a CR in 57%. With a median follow-up of 58 months, the 5-year OS rate was 60% for the entire patient population, with a median OS not reached. Patients in CR fared better, with a 5-year OS of 79%; on the contrary, patients not achieving a CR had a 5-year OS rate of 25%. The 5-year PFS rate for the entire population was 39%, with a median of 20 months; among CR cases, the median PFS rate was not reached, and at 5 years the estimated rate was 57%. Patients with ALCL-ALK$^-$ had similar response and survival rates to those with ALCL-ALK$^+$. Importantly, patients who achieved a CR and who received subsequent consolidative stem cell transplantation had comparable outcomes to those who did not undergo consolidation. Peripheral neuropathy was the most relevant safety concern regarding the treatment with BV. Fifty-seven percent of patients in the study experienced this adverse event, which resolved in 67% of cases or improved (regressed to at least grade 1 or less) in 24%, mainly due to drug withdrawal.[58]

Besides ALCL, a phase 2 study involved 35 patients with mature T-cell lymphoma with variable CD30 expression, among which there were 22 subjects with PTCL-NOS and 13 with AITL. Patients were treated with BV at the standard dose of 1.8 mg/kg every 3 weeks, as reported for Hodgkin lymphoma and ALCL patients. Responses were seen in 41% of cases, with an ORR of 33% for PTCL-NOS and 54% for AITL, and a CR rate of 14% and 38%, respectively. No apparent correlation between CD30 expression and depth of response was documented, as responses could be seen in cases of undetectable CD30 upon centralized pathological review. This means that it is plausible that not much CD30 expression may be related for an effective drug targeting.[59]

Mogamulizumab

Mogamulizumab is a humanized anti-CCR4 monoclonal antibody characterized by a defucosylated Fc region that stimulates antibody-dependent cellular cytotoxicity, with a potent antitumor activity toward T-cell lymphoma cell lines and ATLL mouse models. CCR4 is a marker for type 2 helper T cells and T_{reg} and is expressed on tumor cells in 30% to 65% of patients with PTCL, conferring a worse prognosis when expressed.

The drug was granted approval for ATLL in Japan based on the results of a multicenter phase 2 study conducted on 28 patients relapsed after at least one previous systemic line. In this study, mogamulizumab administered intravenously at the dose of 1.0 mg/kg (as established from the previous phase 1 trial) once a week for 8 weeks determined an ORR of 50%, including 31% CR.[60]

Data on relapsed and refractory $CCR4^+$ PTCL patients are derived from two phase 2 studies conducted in Japan and Europe. The Japanese study showed a higher ORR than observed in the European trial (34% vs. 11%), without an apparent explanation, although PFS was comparable between the two experiences (2.0 vs. 2.1 months, respectively). Toxic effects were also similar, with peripheral cytopenias, skin rash, pyrexia, and infusion reactions being the most frequently observed.[61,62]

Off-Label Compounds

Besides approved agents, other drugs have demonstrated efficacy in patients with various subtypes of PTCL who have failed one or more previous treatment lines. The studies in which these agents have been evaluated have generally involved patients with mixed diagnoses, so that it is difficult to clearly establish if a peculiar PTCL histology may respond more favorably to a specific single agent. Taken together, the results obtained with investigational and off-label compounds in terms of ORR, CR rates, and survival rates are close to what has been already described for the FDA-approved drugs pralatrexate, romidepsin, belinostat, and BV. Nevertheless, most of the trials in which these agents were involved have not been designed to follow patients for survival; therefore, it is difficult to draw definite conclusions on how these molecules effectively impact on disease history, and apart from some favorable response rates, none of these agents has yet proved to ameliorate survival functions in relapsed or refractory patients with PTCL.

Lenalidomide

It is an immunomodulatory drug, working in several hematologic malignancies, including multiple myeloma, with a mechanism of action that mainly rests on 3 principles: (i) antiproliferative effect, mediated by its binding to cereblon ($CRL4^{CRBN}$), which in turns induces the downregulation of IKZF1 and 3 and leads to a decreased expression of NFκB, MYC, and IRF4, an enhanced expression of $p21^{WAF1}$, and the suppression of cell cycle via degradation of cyclin-dependent kinases; (ii) immunomodulation, depending on the increased levels of IL-2 as a consequence of lenalidomide binding to $CRL4^{CRBN}$ in T cells, which consists of an improvement in T-cell and NK-cell antitumor activity; (iii) inhibition of angiogenesis, with a consequent reduced microvessel density within the tumor.

A first phase 2 study evaluating lenalidomide monotherapy in PTCL enrolled 29 patients with relapsed or refractory disease. The drug produced an ORR of 29%, with a median duration of response (DOR) of 5 months.[63] A second phase 2 study focusing on patients with PTCL-NOS showed an ORR of 30%.[64] In a multicenter phase 2 trial with 54 patients conducted in France, the ORR was 22% with a CR rate of 11%. Non-significant slightly higher response was seen in patients with AITL, with an ORR of 33%. The median PFS and the median DOR were 2.5 and 3.6 months, respectively. The most common side effects were hematologic toxicities, with grade 3 to 4 thrombocytopenia and neutropenia observed in 20% and 15% of patients, respectively.[65]

Bendamustine

Bendamustine is a bifunctional compound, structurally consisting of chloroethylamine, an alkylating group, attached to a benzimidazole ring, a purine analog, and a butyric acid side chain that imparts water solubility. Its role in relapsed and refractory PTCL was evaluated at the dose of 120 mg/m^2 (administered intravenously on days 1 to 2 every 3 weeks) in the phase 2 BENTLY trial, which enrolled 60 patients (58 affected by PTCL and 2 by MF). Although 33% of patients could not receive more than 3 cycles mainly due to disease progression, the ORR was 50% with a CR rate of 28%. Responses were seen across multiple histologies, but their duration was short (3.5 months), lasting more than 1 year in only 7% of patients. Grade 3/4 neutropenia and thrombocytopenia were seen in 30% and 24% of patients, respectively.[66]

Gemcitabine

Given as a single agent in a population of older (median age 54 years, up to 78 years) and pretreated (median of three previous treatment lines) patients with relapsed and refractory PTCL-NOS, gemcitabine allowed a very good disease control yielding an ORR of 55% and a CR rate of 50%, with a median response duration of 28 months. No treatment related grade 3 to 4 adverse events were seen; the most frequently reported grade 1 to 2 toxicities were neutropenia, thrombocytopenia, and elevation of liver enzymes.[67] A combination of gemcitabine, cisplatin, and methylprednisolone (GEM-P) was previously tested in an English experience with 16 PTCL patients, yielding a 69% of ORR and a 19% of PR across various disease subtypes.[68]

New Drugs

Demethylating Agents

Recurrent mutations in *TET2*, *DNMT3A*, *IDH2* are known in a relevant percentage of patients with T_{FH} PTCL. For this reason, hypomethylating agents could rationally demonstrate a clinical effect in T_{FH}-derived PTCL, including AITL.[21,22] Recently, the French group reported the outcomes of 12 patients with AITL (all but one with relapsed and refractory disease and in 5 cases with a concomitant myeloid neoplasm), with a median age of 70.5 years, treated with subcutaneous azacitidine at the dose of 75 mg/m^2 given daily for 7 consecutive days, every 4 weeks. Nine patients responded, with a CR in half of the cases and a PR rate of 25%. At a median follow-up of 27 months, the median PFS was 15 months, and the median OS was 21 months, with 5 patients showing a sustained CR lasting more than 2 years.[69]

Ruxolitinib

The JAK-STAT pathway is commonly deregulated in PTCL and mutations in the JAK and STAT system in T-cell neoplasms have been detected in the SH2 domain of STAT3 and STAT5 and in the pseudokinase domain of JAK1 and 3.[11] It can be hypothesized that JAK-STAT pathway alterations, detected as elevated phospho-STAT3 expression or presence of JAK or STAT mutations, will predict the activity of ruxolitinib, a JAK1/2 inhibitor, in patients with PTCL and CTCL. This has been tested in a phase 2 clinical trial in which ruxolitinib, at the dose of 20 mg bid, was given to patients with relapsed and refractory PTCL and CTCL failing at least one previous systemic therapy. The ORR obtained so far are 38% and 40%, respectively in patients bearing JAK or STAT mutations (cohort 1) and functional activation of the JAK-STAT system without concomitant mutations (cohort 2). The observed rate of CR is still low, albeit accrual is ongoing; nevertheless, the observation of objective responses or disease stability for more than 6 months while on treatment provides the rationale of JAK-STAT targeting in T-cell lymphomas.[70]

Duvelisib

PI3K inhibitors block mitogen and prosurvival signals from the tumor and its microenvironment and concomitantly activate an antilymphoma immune response. Duvelisib, an oral dual inhibitor of PI3Kδ and PI3Kγ, was applied as a single agent in a phase 1 trial involving 16 PTCL and 19 CTCL patients with relapsed and refractory disease. The drug was administered on a dose-escalation basis, starting from 25 mg twice daily up to 100 mg twice daily on a 28-day cycle; the maximum tolerated dose was set at 75 mg twice daily, and 77% of the enrolled patients were treated at this dose. In the PTCL population, the ORR was 50%, with 3 CR and 5 PR, all occurring within the first 2 to 4 months of treatment. Responses were seen across multiple histologies, including PTCL-NOS, EATL, and AITL. Median OS and PFS were 8.4 and 8.3 months, respectively. Transaminase elevation was the most relevant adverse event (57% of cases), with grade 3 to 4 toxicity described in 40% of patients. Pharmacodynamic results showed that a down-modulation of serum cytokines and chemokines related to T-cell activation and migration and to the microenvironment (such as CCL22, CXCL13, tumor necrosis factor-α, matrix metallopeptidase-9, and IL-16) occurred within 8 days of starting treatment.[71]

Immunotherapy

The development of checkpoint inhibitors, targeting the interaction of PD-1 with its ligands (namely PD-L1) with subsequent repression of T-cell activation has changed the therapeutic landscape in multiple malignancies. In PTCL, increased expression of PD-L1 has been described in both malignant and stromal cells across various subtypes, thus supporting the rationale of a therapeutic checkpoint-inhibition. Indeed, a PR rate of 40% was described in PTCL patients enrolled in a phase 1b study with nivolumab. Albeit preliminary, this trial suggests further efforts in order to clarify the role of PD-1 blockers in PTCL, alone or in combination with other agents.[72]

Concepts for chimeric antigen receptor (CAR) T cells are being developed for PTCL. However, as pan-T-cell aplasia (the *"fratricide" effect*) causes severe immunodeficiency, the application of CAR-T cells in this context is challenged by the lack of specific antigens discriminating malignant *versus* normal T-lymphocytes. The mutually exclusive expression pattern of the TCR β-chain constant domains 1 and 2 (TRBC1 and TRBC2) might be a promising approach to target neoplastic T cells harboring either TRBC1 or TRBC2 while preserving a substantial proportion of normal T cells.[73]

Allogeneic Hematopoietic Stem Cell Transplantation

Reports on allogeneic hematopoietic stem cell transplantation (allo-HSCT) in patients with T-cell lymphomas are just a few and tend to group together patients with very advanced and often refractory disease and several histology subgroups. Therefore, it is hard to draw conclusions about its clinical impact and no clear distinctions can be operated for different disease subtypes.

The rationale behind allo-HSCT rests on the fact that allogeneic hematopoietic stem cells are free of tumor contamination and that donor-derived immune cells are potentially capable of mediating an antitumor (i.e., graft-versus-lymphoma) effect.[74] This is demonstrated by responses to donor lymphocyte infusions. Disease status at transplantation and chemosensitivity are outcome predictors. Patients in remission at the time of transplantation may achieve a cure and OS curves reach a plateau at approximately 18 months. On the contrary, only 25% to 30% of refractory patients may take advantage of the procedure.

The French group has reported the outcome of 77 patients who received allo-HSCT: the 5-year TRM was 33%, and the 5-year OS and PFS were 57% and 53%, respectively. In this study, most patients received myeloablative conditioning regimen and relatively high TRM was a concern.[74]

Reduced-intensity conditioning (RIC) regimen has become a more standard approach. A phase 2 Italian study of RIC allo-HSCT in 17 patients with relapsed and refractory PTCL showed 3-year OS and PFS rates of 81% and 64%, respectively, with lower TRM rates (6% at 2 years).[75] In a similar study from the United States, again with 17 patients, the 3-year OS and PFS were 59% and 53%, respectively, and the 3-year TRM was 19%.[76] In a Japanese study, 354 patients (200 PTCL-NOS, 77 AITL, and 77 ALCL patients) who received allo-HSCT were retrospectively analyzed: the 3-year TRM rates and the 3-year OS rates in younger patients (16 to 49 years) who received myeloablative regimen were 22% and 43%, respectively, while in those who received a RIC regimen they were 14% and 56%, respectively.[77]

At present, allo-HSCT is feasible in just a few patients with relapsed PTCL, as most of cases are characterized by rapid progression, clinical decay, and chemoresistance, all factors that may preclude a timely and effective application of this approach. Better OS and PFS results are obtained when allo-HSCT is performed early in the course of the disease and after a few treatment lines: this suggests that allo-HSCT should be performed as early as possible in patients with recurrent disease and preferably in chemosensitive individuals.

Future Directions

Advances in the molecular pathology of PTCL have provided the rationale for better classification of patients, more effective prognostic stratification, and ultimately more powerful treatment approaches. Current first-line and salvage therapies for PTCL patients are still largely unsatisfactory. New drugs have offered some improvement in frontline setting and, more importantly, in patients with relapsed and refractory disease. However, response durations are short, and many patients still develop progressive disease while under treatment, thus having no chance for long-term good quality outcomes.

Preclinical models have suggested potent synergy between novel drugs, especially between HDAC inhibitors and pralatrexate, PI3K inhibitors and azacytidine. This means that we have initial evidence that some non-chemo drugs may complement their activity when combined with other drugs active in PTCL. The addition of checkpoint inhibitors to doublets may reinforce the synergistic paradigm in the future, pointing toward the development of lineage-specific and disease-specific chemo-free combinations.

CUTANEOUS T-CELL LYMPHOMAS

CTCL are defined as T-cell lymphomas with exclusive cutaneous involvement, lacking any nodal or extracutaneous disease at the time of their diagnosis. They represent 75% of all primary cutaneous non-Hodgkin lymphomas, with the rest being represented by cutaneous B-cell counterparts. The current classification of CTCL is part of the joint WHO-European Organization for Research and Treatment of Cancer (EORTC) classification of primary CTCL (containing both B- and T-cell lineage diseases). It was first published in 2005 and then included in the 2006 WHO classification of skin tumors, ultimately incorporated in the 2008 WHO classification of tumors of hematopoietic and lymphoid tissues and its subsequent 2017 revision. In August 2018, an updated version of the WHO-EORTC classification (Table 89.10) was published in the fourth edition of the WHO classification of skin tumors, mostly maintaining the same terminology currently applied in the 2017 WHO classification of hematopoietic neoplasms.[78]

MF and SS are the prototypical forms of CTCL: they are closely related to one another, as composed by neoplastic T cells with the capability of infiltrating the skin and variably circulating in peripheral blood or homing to lymph nodes. Although displaying overlapping presentations and a continuous spectrum of evolution from an initial phase of skin-limited disease to a more disseminated and systemic

TABLE 89.11 The T (skin), N (nodes), M (Visceral Involvement), and B (Blood Involvement) Parameters Required for the Staging of Mycosis Fungoides

Skin	T_1	Limited patches, papules, and/or plaques covering <10% of the skin surface. Further stratify into T_{1a} (patches only) and T_{1b} (plaques ± patches).
	T_2	Patches, papules, or plaques covering ≥10% of the skin surface. Further stratify into T_{2a} (patches only) and T_{2b} (plaques ± patches).
	T_3	One or more tumors, ≥1 cm in diameter.
	T_4	Confluence of erythema, covering ≥80% of body surface area.
Nodes	N_0	No clinically abnormal peripheral lymph nodes: biopsy not required.
	N_1–N_3	Clinically and histologically abnormal peripheral lymph nodes (firm, irregular, clustered, fixed nodes, ≥1.5 cm in diameter).
	N_X	Clinically abnormal peripheral lymph nodes; no histological confirmation.
Viscera	M_0	No visceral organ involvement.
	M_1	Visceral involvement (requires histological confirmation; involved organ should be specified).
Blood	B_0	Absence of significant blood involvement: ≤ 5% of peripheral blood lymphocytes are atypical (Sézary) cells.
	B_1	Low blood tumor burden: >5% of peripheral blood lymphocytes are atypical (Sézary) cells, but criteria for B_2 are not met.
	B_2	High blood tumor burden: ≥1000/mmc Sézary cells clonally positive.

IV B	1–4	0–3	1	0–2

presentation, the WHO-EORTC classification considers these two entities separately (see Table 89.10). MF and SS are presented under the same heading in this paragraph, as the diagnostic approach and the disease staging are the same for both conditions. The treatment of these two conditions is strictly based on the stage at presentation. For this reason, it will be discussed by focusing on the extent of the disease (limited stage MF *versus* advanced stage MF/SS).

Primary cutaneous CD30⁺ T-cell lymphoproliferative disorders are the second most common group of CTCL, which includes pcALCL and LyP as two extremities of a disease spectrum. Histologic and phenotypic features are mostly overlapping; thus the clinical presentation of the disease and its clinical course are decisive to discriminate clearly between pcALCL and LyP and to decide treatment.

CTCL other than MF, SS, and primary cutaneous CD30⁺ T-cell lymphoproliferative disorders are very rare, and together account for less than 10% of all CTCL cases. These entities are listed in Table 89.10, but their discussion is beyond the scope of this chapter.

A multidisciplinary approach, requiring the involvement of hematologists, experienced hemopathologists, and dermatologists, is strongly encouraged for the management of patients with CTCL, both at diagnosis and at relapse. Cooperation between specialists is of utmost importance, as most CTCL cases are seen by dermatologists first, who need to establish a correct diagnosis and to manage the patient properly according to the extent of the disease. Skin-directed therapies are suitable in case of limited disease, whereas systemic approaches need to be considered when the disease is diffuse or as soon as it progresses under (or after) an initial conservative approach. Systemic treatments are generally administered in a hematology setting. For this reason, they are treated in more detail in this section of the chapter.

Mycosis Fungoides and Sézary Syndrome

MF is characterized by the presence of mature T-lymphocytes, in most cases with a T-helper phenotype, that infiltrate the epidermis in early stages of disease (giving rise to flat or slightly scaly lesions, or patches) or have acquired the capacity to proliferate and invade the dermis (plaques and tumor stages), with possible dissemination to internal organs. SS is the leukemic counterpart of MF. Its classic features are represented by erythroderma (i.e., diffuse reddening of the skin) with hyperkeratosis of palms and soles, lymphadenopathy, and presence of atypical circulating T-lymphocytes with grooved and lobulated cerebriform nuclei (Sézary cells). Patients initially presenting with classic MF lesions—i.e., patches or plaques—may eventually evolve to an erythrodermic and leukemic phase, thus meeting the clinical and diagnostic criteria for SS (being referred to as having leukemic MF or secondary SS). Alternatively, SS may arise *de novo* as a disease independent from a previous MF phase.

Although biologically different (discussed later in the chapter), MF and SS represent a continuous disease spectrum, as clearly emerges from staging criteria (Tables 89.11 and 89.12). In other words, all patients with a high blood burden of disease—if Sézary cells are at least 1000/mmc (B_2 disease, stage IVA) or represent at least 20% of circulating lymphocytes (some of the B1 disease cases, stage IIIB)—are diagnosed with SS, whereas in all other instances the diagnosis is MF (with stage IVA and IVB MF being defined as nodal or visceral MF, respectively).

MF has an incidence of 5.6 cases per million people in Western countries, whereas the age-adjusted incidence of SS is 0.1 per million. Importantly, the incidence of these diseases in a well-defined population strictly depends on the awareness of dermatologists in recognizing such entities and in performing a correct diagnosis and staging workup. They are largely a disease of the middle-aged and elderly people, with highest incidence above 70 years; nevertheless, increased awareness of the disease has led to earlier diagnosis even in much younger patients. Blacks have a higher incidence rate than Caucasians; their onset seems to be earlier and the clinical outcomes appear much worse.

Morphology

Early patches of MF display small lymphocytes scattered in the papillary dermis or around the venules of the superficial plexus; a few of them are within the epidermis. As patches develop, the papillary dermis becomes fibrotic and the lymphocytic infiltrates become denser and band-like, at least in foci. Cells also begin to show atypical features, mostly irregular cerebriform nuclei, which helps in the differential diagnosis with inflammatory conditions. MF cells typically colonize the basal layer of the epidermis and diffuse along the dermoepidermic junction, with a tendency to climb upward (epidermotropism), sometimes forming small lymphocytic aggregates within the epidermis, known as Pautrier microabscesses (Fig. 89.7). Plaque stage is characterized by a significant number of lymphocytes with atypical nuclei and sometimes by prominent collections of lymphocytes in the epidermis. Tumors of MF are consistent with a diffuse replacement of the reticular dermis by atypical lymphocytes, sometimes with aspects of transformation into larger cells with abundant cytoplasm, large oval vesicular nuclei, and prominent nucleoli, as happens in ALCL. The typical phenotype of MF cells is $CD3^+$, $CD4^+$, $CD8^-$, $CD45R0^+$, and most often negative for CD7 and PD1. CD30 is expressed in some MF cells, mostly in tumors enriched with large cells; its expression displays wide variability among lesions even in the same patient.

The histological features of SS overlap with those of MF as far as the cytological details are concerned. SS lymphocytes are generally smaller than MF ones and tend to localize around the small vessels in the superficial dermis, sometimes forming small Pautrier abscesses. On genetic grounds, complex karyotypes are found in many cases, especially in those presenting with more advanced stages.

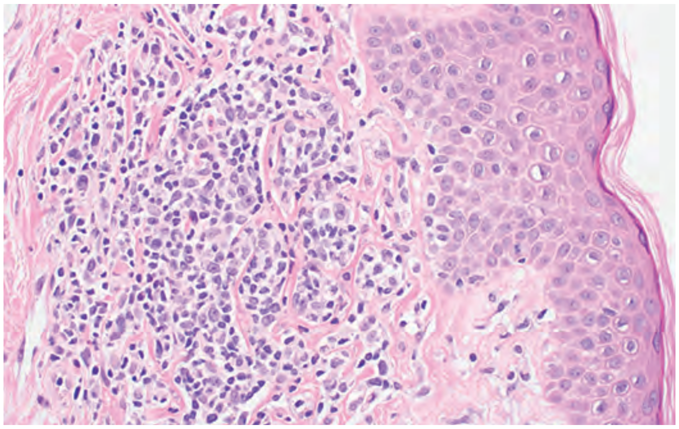

Figure 89.7 MYCOSIS FUNGOIDES, SKIN BIOPSY, HEMATOXYLIN-EOSIN STAINING.

Pathobiology

MF and SS classically arise from skin-tropic memory $CD4^+$ cells; $CD8^+$ or $CD4^-/CD8^-$ cells can also be encountered. The demonstration of different T-cell immunophenotypes and molecular profiles, however, supports the hypothesis that these two malignancies originate from distinct memory T-cell subtypes. More precisely, MF seems to originate from skin resident memory T cells (T_{RM}), whereas SS is a neoplasm of skin-tropic central memory T cells (T_{CM}). This distinction may also explain their peculiar clinical features, as it refers to their tendency to migrate from lymph nodes to blood and skin, and vice versa.[79,80]

When naive T cells residing in skin-draining lymph nodes encounter their cognate antigen, they proliferate clonally as effector T cells and ultimately to memory T cells. Effector T cells express the cutaneous lymphocyte antigen (CLA), a skin-homing receptor that interacts with E-selectin on endothelial and epidermal cells, which favors their translocation from blood to skin and their specific skin tropism. Moreover, they express the C-C chemokine receptor 4 (CCR4), which in turn cooperates in their migration by binding to chemokines produced by the skin itself, such as CCL17 and CCL22. Skin T_{CM} cells also express CCR7 and L-selectin, which is responsible for their circulation between skin and blood and blood and lymph nodes. Once they have migrated to the skin, in other words, they are able to turn back to the blood stream and then to lymph nodes through high endothelial venules, following the interaction between CCR7 and its ligands CCL19 and CCL21 (Fig. 89.8). Skin-resident T_{RM} cells, on the other hand, lack L-selectin and CC7, albeit displaying CLA and CCR4. For this reason, they rarely circulate out of the skin. A third subset of cells, termed migratory memory T cells (T_{MM}), expresses CCR7 but not L-selectin and perhaps has the capability of recirculating more slowly out of the skin toward blood and lymph nodes, compared to T_{CM} cells.[79,80]

Given that T_{RM} cells are non-migratory populations, they constitute fixed skin lesions with well-defined borders; this is what happens in MF patients. On the contrary, the tendency of T_{CM} to recirculate between several compartments explains the diffuse erythroderma of SS patients, which is accompanied by lymph node enlargement and leukemic presentation. Patients with a T_{MM} phenotype have ill-defined but discrete skin lesions.

Clinical Manifestations

MF follows a stagewise progression from patches and plaques to thicker tumor lesions to diffuse erythroderma. Patches are generally round or oval, sometimes they may be digitated, and they vary in size (from 1 cm to more than 10 cm). They can be confined to a limited area—predominantly in sites protected by sunlight—or may show a tendency to disseminate in the former case; the disease generally behaves indolently, requiring no treatment for long periods of time (Fig. 89.9). Plaques present as red-to-brown flat or raised indurated and sometimes ulcerated areas that can further evolve into tumors; the latter are nodular lesions developed on pre-existing patches or plaques, with a high tendency to ulceration and bleeding (Fig. 89.10). The evolution of the disease into progressive stages indicates its increased aggressiveness over time.

Blood involvement is the main characteristic of SS. Erythroderma is the key feature of SS, characterized by a diffusely erythematous and desquamating skin (Fig. 89.11) along with hyperkeratosis of palms and soles, skin fissuration, and loss or dystrophy of nails.

Diagnosis and Staging

Diagnosis is established upon skin biopsy within a compatible clinical context. Immunohistochemistry is also useful to confirm the diagnosis, as well as detection of TCR rearrangements. These elements help discriminate MF from drug reactions, connective tissue diseases, lichen *sclerosus et atrophicus*, and inflammatory dermatoses.

Figure 89.8 THE ONTOGENY OF MYCOSIS FUNGOIDES (MF) AND SÉZARY SYNDROME (SS). Epidermotropism and homing to blood and lymph nodes are the main charactF and SS cells, respectively, which reflect onto clinical features of these diseases. See text for abbreviations and explanation.

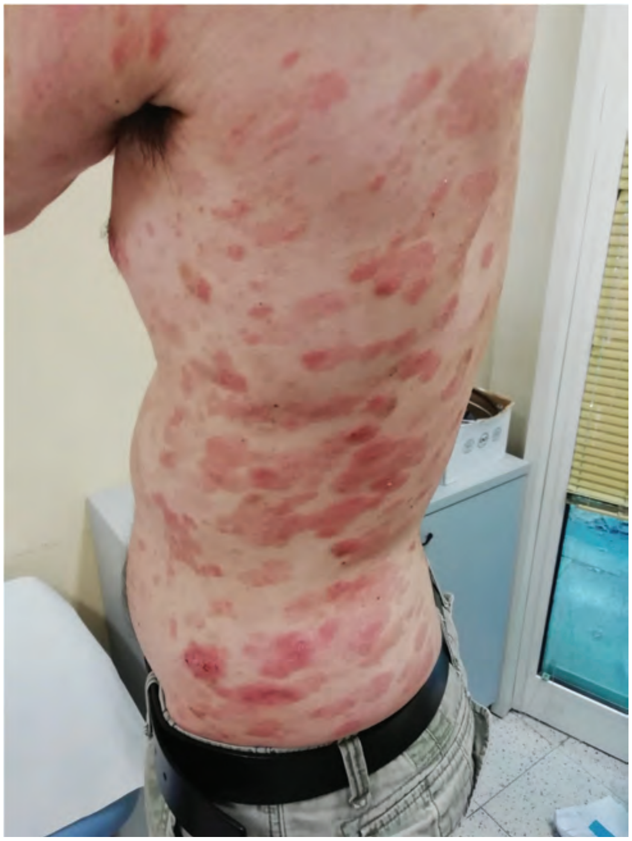

Figure 89.9 MYCOSIS FUNGOIDES, DISSEMINATED PATCHES AND PLAQUES.

SS is diagnosed when Sézary cells are ≥1000/mmc or represent at least 20% of circulating lymphocytes. Detection of TCR rearrangement is required to establish the diagnosis of SS, along with the flow cytometric demonstration of the typical phenotype (generally with a CD4/CD8 ratio ≥10). SS should be placed in differential diagnosis with erythrodermic allergic contact dermatitis and drug eruptions. The clinical approach to the patient is described in the box on Clinical Approach to a Patient Affected by MF or SS and Staging Recommendations.

Prognosis

Outcomes are related to the extent of skin, blood, lymph node, and visceral involvement, according to the TNMB system. Patients with patches of MF covering less than 10% of the body surface area (T_1) have a very indolent disease and their life expectancy is generally unaffected. Those with more diffuse involvement are more likely to develop plaques or tumors (T_3, stage II B and higher). In general, patients with stages I to II A (T_1–T_2) have a "limited-stage" disease and their lifespan is measured in decades. Patients with tumors, blood involvement (B_1–B_2), erythroderma (T_4), nodal and visceral (M_1) involvement have an "advanced-stage" disease, and their survival is severely affected (median OS of 1 to 5 years).

Treatment of Limited-Stage MF

Limited-stage disease is mostly asymptomatic, especially if limited body surface is affected by patches or plaques. For this reason, it is generally managed conservatively. A "watch and wait" policy is considered adequate in many cases, whereas skin-directed therapies are the mainstay of treatment in cases of symptomatic disease or in patients who

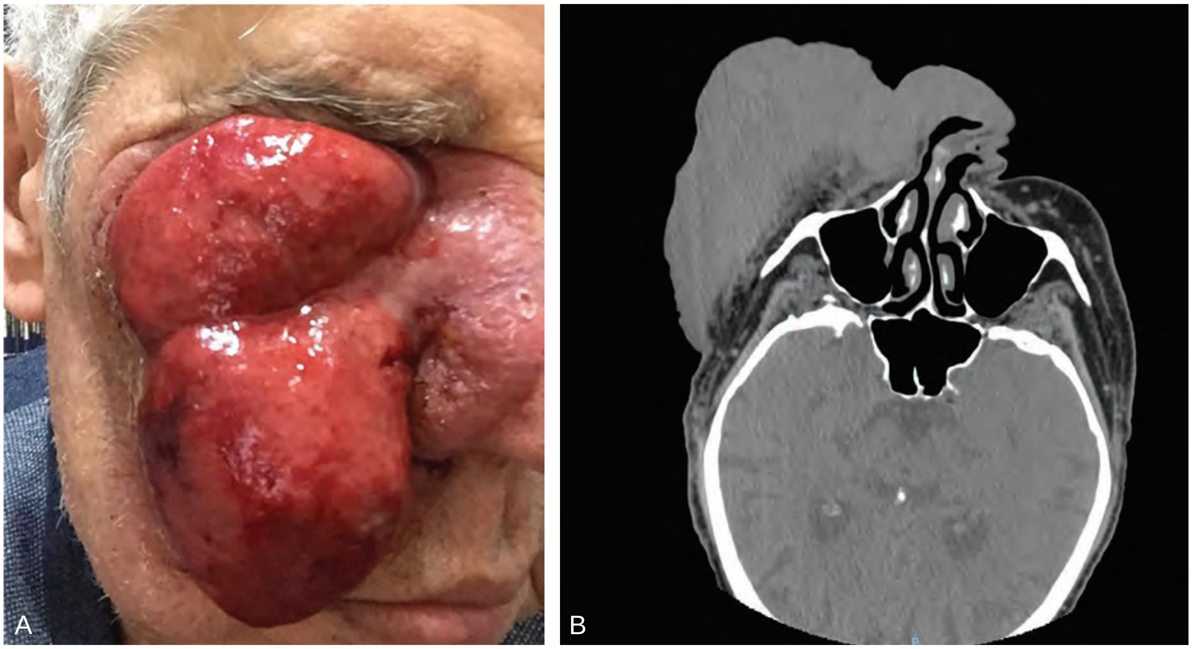

Figure 89.10 MYCOSIS FUNGOIDES. (A) Tumor stage. (B) Computed tomography scan of the head of the same patient showing marked compression and deviation of the nasal pyramid.

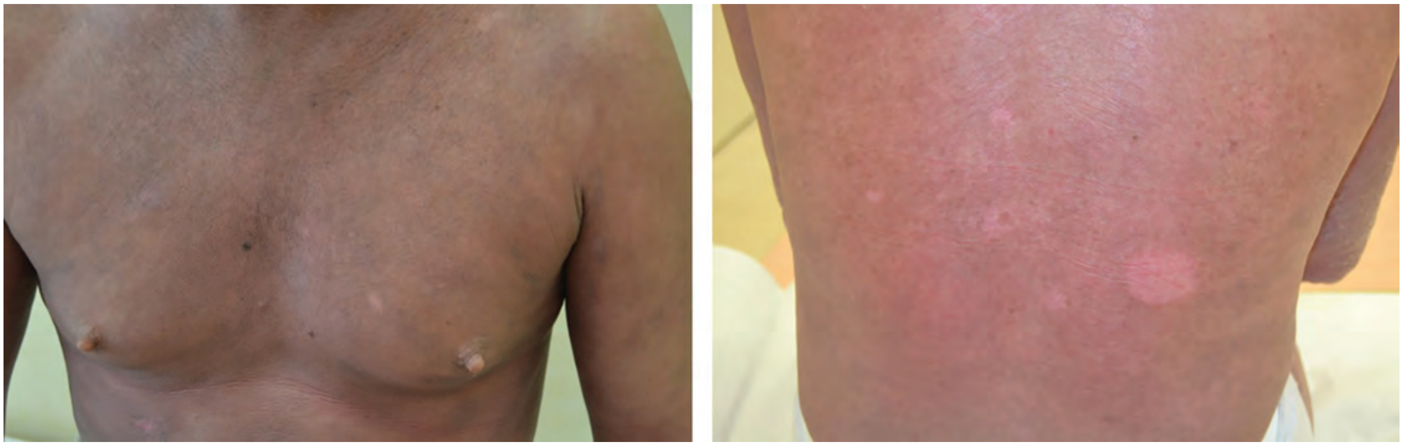

Figure 89.11 ERYTHRODERMA IN A PATIENT WITH SÉZARY SYNDROME.

develop extensive skin involvement. Patient management is addressed at the control of local symptoms and preserving a good quality of life, avoiding treatment-related toxicities. (See box on Treatment Approach to MF and SS Patients According to Stage at Presentation.)

Dermatologists and radiation oncologists mainly guide treatment at this stage. For this reason, only the most widely applied treatment strategies are briefly reviewed here.

Topical Treatments

Topical steroids represent the most widely applied first-line treatment in localized disease. Clobetasol propionate (cream or ointment) is able to produce high response rates, up to 90% in patients with T_1 disease and 80% in those with T_2 disease, with side effects (like purpura or irritant dermatitis) emerging in case of prolonged treatment.[81]

Topical toll-like receptor (TLR) agonists stimulate the innate immune system to harness an anti-lymphoma effect by the production of cytokines such as IFN α and IL-12, which are capable of inducing cell death and promoting host anti-tumor immunity. Topical 5% imiquimod, a TLR7 agonist, has shown activity in limited-stage MF. In a cohort of 20 patients treated with this agent, responses were observed in 80% of the cases, with a CR rate of 45%. Local toxicities were limited to localized pain and redness, pruritus, or ulceration, whereas systemic symptoms were just occasional.[82]

Mechlorethamine gel, 0.02%, demonstrated its efficacy in 58% of MF patients (76 patients out of 130) after at least 6 months of treatment compared with 48% of patients (62 out of 130) who used the ointment. A CR was obtained in 14% of treated patients. The most commonly reported side effects were dermatitis (skin inflammation with reddening, rash, pain or burning sensation), skin infection, and itching.[83]

Phototherapy

It is used alone or in combination with other agents (such as topical therapies, interferon, or bexarotene) in patients with limited-stage disease and with extensive skin involvement. Narrowband ultraviolet B (NB-UVB) has been used on both patches and plaques in limited-stage disease until clearance or plateau in response, with reported CR rates ranging from 54% to 90%, 84% on average. Patients with patch-only disease seem to perform better than those with plaques.

Relapse-free intervals reported in literature vary between 5.9 to 14.5 months, but they can be extended up to 26 months if any form of NB-UVB maintenance is applied. Treatment with 8-methoxypsoralene (8-MOP) plus ultraviolet A (PUVA) has produced very variable response rates in patients with limited-stage disease, with CR rates ranging between 65% and 85%. Patches and thin plaques are known to respond better to PUVA than thick and more infiltrated plaques, according to the experience of experts. However, PUVA should be preferred to NB-UVB treatment in plaque-stage disease because of the superior penetration of skin of ultraviolet A. Time-to-response is generally 2 to 3 months and seems to be largely stage-independent.[84]

CLINICAL APPROACH TO A PATIENT AFFECTED BY MF OR SS AND STAGING RECOMMENDATIONS

1. Skin examination with determination of type(s) of skin lesions (patches, plaques, tumors, erythroderma), along with skin ulceration or fissuration, hyperkeratosis or nail changes. Estimate the percentage of body surface area involved.
2. Complete physical examination: identification of any palpable lymph node, especially those larger than 1.5 cm or firm, irregular, clustered, or fixed; palpation of any organomegaly.
3. Skin biopsy. Most indurated area if only one biopsy is performed. Special immunohistochemistry staining: CD30, to be considered if lymphomatoid papulosis, anaplastic lymphoma, or large-cell transformation is suspected; CCR4 if treatment with mogamulizumab is planned. Evaluate for clonality of T-cell receptor gene rearrangement.
4. Laboratory: complete blood count with differential counts (including the examination of a peripheral blood smear to evaluate for Sézary cells), liver and renal function tests, lactate dehydrogenase. Flow cytometry (including $CD4^+/CD7^-$ or $CD4^+/CD26^-$).
5. Staging procedures: computed tomography (CT) scan of neck, chest, abdomen, and pelvis with intravenous contrast (it can be omitted in patients with T_1 and limited T_2 disease, with N_0 and B_0, and replaced by chest X-ray and abdomen ultrasonography); unilateral bone marrow trephine biopsy (mandatory in case of concomitant peripheral blood abnormalities).
6. Lymph node biopsy: excisional biopsy is indicated in those patients with a lymph node either larger than 1.5 cm in diameter and/or is firm, irregular, clustered, or fixed.

Total Skin Electron Beam Irradiation

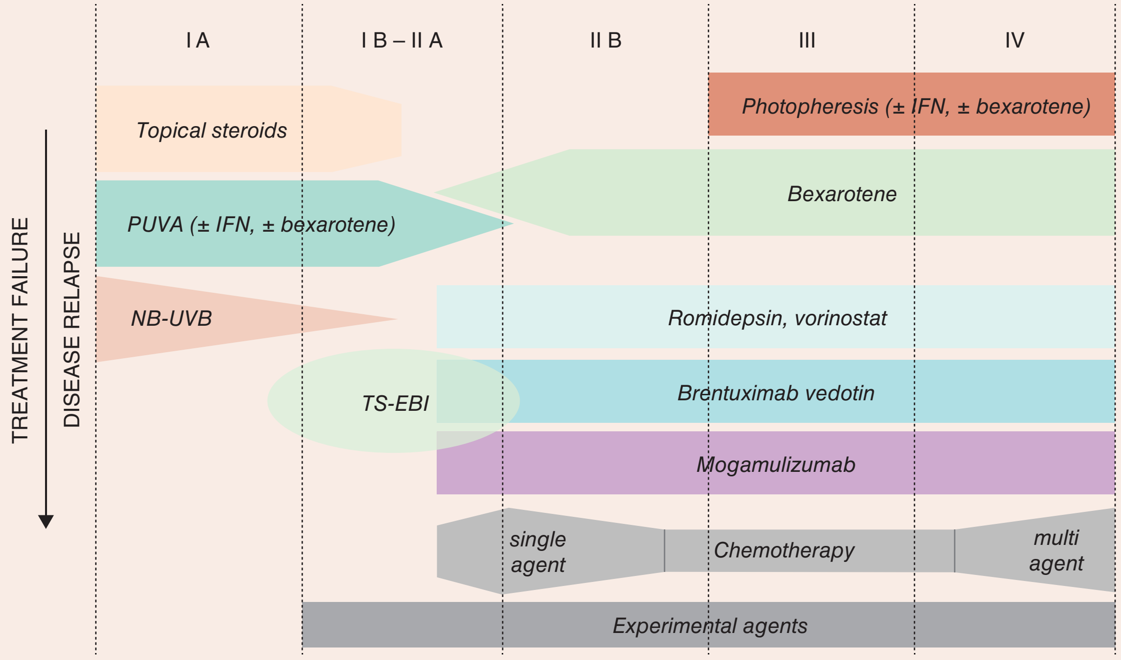
Total skin electron beam irradiation (TS-EBI) is the single most effective skin-directed therapy for MF. Conventional TS-EBI doses range from 24 to 36 Gy, as the rate of CR improves according with dose increase. Toxicity is however dose-dependent and common adverse events consist of erythema, dry desquamation, temporary anhidrosis, and temporary loss of fingernails and toenails. Alopecia may be irreversible at doses exceeding 25 Gy. Most patients display disease relapse, even after 36 Gy. However, repeated courses of high-dose TS-EBI are administered reluctantly because of the significant risk of skin atrophy and xerosis. For this reason, TS-EBI has been applied at lower doses in order to perform shorter treatment courses, reduce radiation-related adverse events, and possibly apply the treatment more than once as soon as patients relapse. It has been demonstrated that low-dose TS-EBI in the ranges of 10 to 20 Gy or 20 to 30 Gy were comparable with doses of 30 Gy or more. Indeed, an ORR of 88% was documented in a pooled analysis of 3 clinical trials of 12 Gy TS-EBI, with transient and manageable side effects, although the CR rate was significantly lower than with 36 Gy.[85]

Treatment of Advanced-Stage MF and SS and Management of Relapsed Disease

The management of advanced-stage disease patients is based on the close cooperation between hematologists, dermatologists, and radiation oncologists. The same happens in patients with relapsed or

TREATMENT APPROACH TO MF AND SS PATIENTS ACCORDING TO STAGE AT PRESENTATION

- Skin-directed treatments are applied in limited-stage disease and may be repeated as soon as disease relapses.
- Systemic treatments need to be considered in case of advanced-stage disease at presentation or relapse.
- Enrollment in clinical trials is always encouraged, especially for patients with multiple relapsing disease.



refractory disease. Goals of therapy are to control symptoms, maintain cosmesis, and improve survival by maximally reducing the tumor burden.

Biologic-response modifiers, like bexarotene, and HDAC inhibitors are applied as early treatment lines in advanced disease, while systemic treatments with BV or mogamulizumab are appropriate in patients lacking proper responses and with relapsed disease. Systemic chemotherapy may also play a role, especially in patients with disseminated visceral disease and bulky masses. However, published experience is scarce and responses are not durable, as response durations are generally measured in months.

Despite the availability of several active systemic therapeutic strategies, there is still an unmet need for treatments with favorable therapeutic indices. As treatment of advanced-stage MF and SS is largely palliative, a stage-based approach applying sequential therapies in an escalated fashion is preferred. Participation in a well-designed clinical trial is encouraged, as the introduction of novel agents will continue to expand the therapeutics options available in the management of CTCL.

Here we review the agents approved for the treatment of advanced-stage and relapsed or refractory MF and SS. (See box on Treatment Approach to MF and SS Patients According to Stage at Presentation.)

Bexarotene

It is an orally available synthetic retinoid capable of binding and activating retinoid X receptors (RXR), which are in turn responsible for changes in gene expression that lead to cell differentiation, decreased cell proliferation, and apoptosis. Bexarotene was approved by the FDA for the treatment of CTCL in 1999; later, a topical gel formulation of bexarotene was also approved, even though it is not available everywhere.

Bexarotene was tested in a multicenter phase 2/3 trial in 94 patients with biopsy-confirmed CTCL in advanced stages (IIB-IVB) who had received previous treatment for their disease; 56 patients received an initial dose of 300 mg/m^2/day and 38 started at a higher dose (>300 mg/m^2/day). Clinical responses were reported in 45% of patients (25 out of 56) enrolled in the 300 mg/m^2/day group, although with only 2% of them achieving a CR. Among those who received a higher dose, 55% (21 of 38) responded, including 13% clinical CR. Despite this, dose-limiting toxicity was far more common in patients receiving doses higher than 300 mg/m^2/day, thus the 300 mg/m^2/day dose appeared to provide the optimal risk-to-benefit ratio. Importantly, hypertriglyceridemia and central hypothyroidism were noted as the most frequent adverse events. Therefore, patients on bexarotene treatment need to have their basal free T4, thyroid-stimulating hormone, and serum lipid concentrations measured and monitored throughout treatment. Moreover, the use of lipid-lowering drugs (as fenofibrate) and adequately titrated doses of L-thyroxine is suggested before treatment initiation. In the 300 mg/m^2/day initial dose group, the rate of relapse after response was 36% and the projected median DOR was 299 days. Responses are generally seen within 2 to 3 months of treatment. Treatment should be carried on for at least 6 months and maintained until disease progression or unacceptable toxicity.[86]

Combination of bexarotene with PUVA or extracorporeal photopheresis (see below) can also be an option.

Histone Deacetylase Inhibitors

Vorinostat (suberoylanilide hydroxamic acid, SAHA) and romidepsin (depsipeptide) are class I and II HDAC inhibitors active in CTCL. Their mechanism of action is summarized in the section on treatment of relapsed and refractory PTCL.

Following the initial dose-finding study, which established 400 mg daily of vorinostat as the optimal dose to be further investigated, this drug was evaluated as a single agent in a phase 2b multicenter trial that included 74 patients with stage I B-IV A MF or SS who had received at least two prior systemic therapies including bexarotene (unless this drug was not tolerated). Disease stage was at least II B in 61 patients. Patients were treated with 400 mg of oral vorinostat daily until disease progression or intolerable toxicity. The ORR was approximately 30% in patients with advanced-stage disease, and all the initial responses were PR, with one CR. Up to 36% of patients with SS achieved a response. The median time to response in stage IIB or higher patients was 56 days, with a median response duration longer than 185 days. Median time to progression (TTP) was 4.9 months overall and longer than 9.8 months for stage IIB or higher responders. Among patients who failed to achieve a clinical response, pruritus relief, decreased lymphadenopathy, and reduction of leukemic tumor burden could be appreciated.[87]

Romidepsin was evaluated in two phase 2 international multicenter trials. The first trial involved 71 patients who had undergone a median of four prior treatments. Advanced-stage disease (higher than II B) was documented in 62 patients (87%), with 41 patients with stage IV. Romidepsin was administered at the dose of 14 mg/m^2 on days 1, 8, and 15 every 28 days. CR were observed in 4 patients and PR in 20, yielding an ORR of 34%. The median DOR was 13.7 months.[88] The second study involved 96 MF and SS patients with stage IB to IVA. Most patients (71%) had advanced-stage disease. The ORR was 34%, including six patients with CR. Among patients with advanced-stage disease, the ORR was 38%, including 5 CR. The median time to response was 2 months and the median DOR was 15 months. A clinically relevant improvement in pruritus was seen in 43% of cases even if lacking a clinical response.[89]

Brentuximab Vedotin

An initial phase 2 study of BV in CTCL reported its activity in CTCL and LyP, with an ORR of 73% and a CR rate of 35%. Fifteen of 28 patients with MF responded (54%), across a wide range of CD30 expression. Importantly, the ORR was 50% in patients with low CD30 expression (<10%), 58% in those with a medium expression (10% to 50%), and 50% in case of high expression (>50%). Time to response was 12 weeks (range, 3 to 39 weeks), and DOR was 32 weeks.[90] Another phase 2 study reported an ORR of 70% in advanced MF and SS with a wide range of CD30 expression levels, again underlying that responses were seen independently of CD30 expression within the affected tissue.[91]

In patients with previously treated MF and cutaneous ALCL, BV used as a single agent at the standard dose of 1.8 mg/kg every 21 days has demonstrated superior activity in disease control over standard treatments (oral methotrexate, 5 to 50 mg/week or oral bexarotene, 300 mg/m^2 once daily). In a phase 3, multicenter, randomized trial (ALCANZA), 64 patients received BV and 64 standard treatment according to physician's discretion (population evaluable for efficacy). The primary endpoint of the study was the proportion of patients who achieved an objective global response (skin + nodes + blood) lasting at least 4 months (termed ORR4) per independent review facility. At a median follow-up of 23 months, the ORR4 was 56.3% in patients treated with BV *versus* 12.5% in those receiving standard treatments ($P < .0001$). Median PFS was 16.7 months in the BV group and 3.5 months in the physician's choice group (Fig. 89.12). These results granted BV approval in patients with MF and cutaneous ALCL who have received at least one previous systemic treatment line.[92]

Mogamulizumab

A phase 1/2 open-label multicenter randomized clinical trial demonstrated an ORR of 47.1% in SS patients and 28.6% in MF patients. Importantly, the treatment determined a rapid clearance of malignant cells as measured by flow cytometry in 18 of 19 patients with blood involvement.[93] In the Japanese phase 2 study, also including PTCL patients, a 50% ORR was reported in the CTCL cohort.[67]

Figure 89.12 PROGRESSION-FREE SURVIVAL IN PATIENTS TREATED IN THE BRENTUXIMAB VEDOTIN ARM COMPARED TO THOSE IN THE PHYSICIAN'S CHOICE ARM. *(Reprinted with permission from Elsevier, Prince HM, et al. Brentuximab vedotin or physician's choice in CD30-positive cutaneous T-cell lymphoma (ALCANZA): an international, open-label, randomised, phase 3, multicentre trial . Lancet. 2017;390:555–566.)*

In a phase 3 randomized trial (MAVORIC), mogamulizumab was compared to vorinostat in 372 patients with relapsed or refractory MF or SS. Mogamulizumab was administered at the dose of 1.0 mg/kg intravenously on a weekly basis for the first 28-day cycle, then on days 1 and 15 of subsequent cycles, while vorinostat was given orally at the dose of 400 mg/day. Patients treated with mogamulizumab showed a statistically significant superior PFS compared to those receiving vorinostat (7.7 *vs*. 3.1 months, respectively). Of note, mogamulizumab was also superior to vorinostat in terms of response rate and duration by disease compartment, i.e., blood, skin, and lymph nodes, as it produced a best global overall response of 35% (*versus* 6% obtained with vorinostat) and at least a 50% improvement in skin response in 44% of cases (*versus* 22% with vorinostat). Importantly, among the 136 patients initially treated with vorinostat who crossed over to mogamulizumab due to lack of efficacy or intolerable toxicity of the drug, 31% achieved an overall response. These findings led to the FDA approval of mogamulizumab for MF and SS patients who have failed at least one prior systemic therapy.[94]

Extracorporeal Photopheresis

Extracorporeal photopheresis (ECP) is based on the extracorporeal irradiation of patient's leukapheresis and plasmapheresis products which are subsequently reinfused. The whole blood of the patient is initially collected, then leukocytes are separated from plasma and non-nucleated cells. Leukocytes are then exposed to ultraviolet A (UVA) irradiation in the presence of a photosensitizing agent, 8-MOP, through a 1 mm thick disposable cassette, prior to reinfusion to the patient.

Psoralen binds covalently to DNA after UVA exposure, thus forming DNA crosslinks. Originally, the primary hypothesis stated that the formation of DNA crosslinks was responsible for apoptosis in the treated immune cells by mechanisms involving the BCL-2 family members, the disruption of mitochondrial membrane potential, and the activation of extrinsic cell death pathways. More recently, this view was enriched by evidence that ECP is capable of dendritic cell initiation, modification of the cytokine profile, and stimulation of several T-cell lineages, in particular regulatory T cells. This ultimately favors antigen presentation and initiation of a host immune response.

The first experience with ECP in patients with SS showed a response rate of 55.7% and a CR rate of 17.6%. A better response rate was found in patients with lower counts of Sézary cells and low CD4/CD8 ratio.[95] Following these results, ECP was approved by the FDA in 1988 for the frontline treatment of SS and erythrodermic MF with blood involvement. Since that preliminary experience, no randomized clinical trials showing the superiority of ECP over other treatment modalities have been performed. However, experience in more than 500 patients from several case series confirms its efficacy with a range of responses between 33% and 74%, with CR rates of approximately 20%. According to current guidelines, ECP should be performed for 2 consecutive days every 4 weeks. More accelerated regimens showed no clear evidence of increase in response rates. It is important to remember that long-term ECP may cause iron deficiency anemia due to a small residual blood volume that is not returned to the patient after each procedure.[96]

Systemic Chemotherapy

Gemcitabine (1000 mg/m^2 once per week for 3 weeks followed by one week of rest, up to 6 cycles) produced an ORR of 68% in 25 patients with advanced-stage and refractory MF and proved to be particularly active in patients with cutaneous tumors.[97] In a retrospective series of 19 MF patients, the same schedule determined an ORR of 48% (with CR and PR rates of 16% and 32%, respectively) with durable responses (15 to 120 months).[64]

Pegylated liposomal doxorubicin was first evaluated more than 20 years ago in 10 patients with MF (stage IB to IVA), who were treated at the dose of 20 mg/m^2. The drug produced an ORR of

80% as a single agent, with a CR rate of 60%. Mean DFS was 13.3 months. In a prospective phase 2 trial enrolling 49 MF patients with stage IIB, IVA, or IVB, refractory or recurrent after at least two previous systemic therapies, responses to liposomal doxorubicin (20 mg/m^2 on days 1 and 15, every 28 days) were seen in 40.8% of the cases; continuous complete remissions were obtained in 6.1% of the patients. A 50% or greater reduction of cutaneous manifestations was observed in 60.5% of treated patients. The median TTP and median DOR were 7.4 and 6 months, respectively.[98]

Primary Cutaneous CD30$^+$ T-Cell Lymphoproliferative Disorders

They are a wide spectrum of indolent T-cell lymphoproliferative disorders, primarily localized to the skin. They account for nearly 30% of CTCL, thus representing the most frequent disease entities after MF and SS, and overall they account for nearly 10% of cutaneous lymphomas. Clinically, they display a chronic clinical course, with cutaneous lesions sometimes showing a relapsing-remitting behavior or spontaneous regressions, and always feature the presence of large and atypical CD30$^+$ cells variably represented within the histological specimen. Primary cutaneous anaplastic large-cell lymphoma (pcALCL) and LyP represent the two extremities of the spectrum and are discussed in more detail. Diagnosis always relies on skin biopsy, which always needs to be reviewed by an expert hematopathologist and then correlated with the clinical presentation. Differential diagnosis is with insect bites and drug eruptions, as well as folliculitis, contact dermatitis, or molluscum contagiosum, all of which may show significant proportions of CD30$^+$ atypical cells on skin biopsies.[99,100]

Primary Cutaneous Anaplastic Large-Cell Lymphoma

pcALCL is the second most common type of CTCL, being mostly represented in middle-aged men (median age at presentation is 60 years, with a male-to-female ratio of 2 to 3:1). pcALCL needs to be distinguished from secondary involvement of systemic ALCL: this is relevant, as the two conditions are treated differently and their prognosis is markedly different, with the former displaying a 10-year disease-specific survival rate of nearly 90%, while the other is a much more aggressive and severe disease (see related paragraph).

Morphology

Tumor cells are large, with an anaplastic (abundant cytoplasm, round to oval or irregularly shaped nuclei with prominent nucleoli), pleomorphic, or immunoblastic cytomorphology. The infiltrate can be either nodular or diffuse; it involves the dermis, sometimes the upper subcutaneous tissue, without epidermotropism. Cells mostly display a CD4$^+$ T-cell phenotype, being CD8$^+$ in a minority of cases, with possible loss of CD2, CD5, or CD3. CD30 is expressed by the majority (>75%) of the neoplastic cells. Multinucleated giant cells found within the neoplastic tissue may mimic Reed-Sternberg cells, thus causing possible confusion with Hodgkin lymphoma; CD15, however, is negative. Cytotoxicity markers, such as TIA-1, perforin, and granzyme B are frequently expressed. The ALK antigen is usually negative, in contrast with ALCL. Clonal rearrangements of the TCR are common and can be found in nearly 90% of cases.

Clinical Manifestations

It clinically presents with solitary and localized papules, nodules, or tumors, frequently ulcerated, involving the skin of trunk, face, extremities, and buttocks. Mucosal surfaces can also be affected. Multifocal involvement is rather uncommon, as no more than 20% of patients have multiple or disseminated lesions. Lesions may show a spontaneous complete or partial regression; however skin relapses are frequent. Extracutaneous dissemination is rare, accounting for less than 10% of the cases, with regional lymph nodes being the most affected tissue other than the skin.

Disease staging differs from the conventional Ann Arbor staging system used for nodal lymphomas and from the TNMB system applied in MF and SS (Table 89.13). This peculiar staging system, also used for LyP, has clinical validity in pcALCL as it clearly separates patients with limited skin involvement from those with more diffuse involvement, with relevant prognostic implications.

Therapy

Localized lesions favorably respond to radiation therapy (with CR rates up to 95%) and topical steroids. Surgical excision may be curative in some cases. pcALCL with regional lymph node involvement may benefit from BV treatment, as do patients with widespread localized (T_2) or generalized (T_3) lesions and relapsed disease. In the phase 3 ALCANZA study, among 16 patients with pcALCL, an ORR of 89% with 44% CR rate was obtained in patients with skin-limited disease, and an ORR of 57% was seen in patients with extracutaneous disease as well.[92] These results appear much more significant than those obtained with bexarotene and oral methotrexate.[99,100]

Prognosis

The prognosis is good, with a 5-year DFS higher than 90%, although relapses are frequent. Patients with multifocal skin lesions and patients with involvement of regional nodes show a similar prognosis to those presenting with a unique skin lesion. Exceptions are represented by patients with extensive lower limb or generalized skin involvement, older age, lack of spontaneous remission, and disease arising in the context of immunosuppression after solid organ transplantation.

TABLE 89.13 **The Proposed TNM Staging System for Patients with Primary Cutaneous ALCL and Lymphomatoid Papulosis**

Skin	T_1	Solitary skin involvement. Further stratify into T_{1a} (solitary lesion <5 cm in diameter) and T_{1b} (solitary lesion >5 cm in diameter).
	T_2	Regional skin involvement, with multiple lesions limited to one body region or two contiguous body regions.[a] Further stratify into T_{2a} (all lesions confined within a 15 cm diameter circular area), T_{2b} (all lesions confined within a >15 cm but <30 cm diameter circular area), and T_{2c} (lesions spread over a >30 cm diameter circular area).
	T_3	Generalized skin involvement. Further stratify into T_{3a} (multiple lesions involving two con–contiguous body regions) and T_{3b} (multiple lesions involving ≥3 body regions).
Nodes	N_0	No clinical or pathologic lymph node involvement.
	N_1	Involvement of one peripheral lymph node region[b] that drains an area of current or prior skin involvement.
	N_2	Involvement of ≥2 peripheral lymph node regions or involvement of any lymph node region that does not drain an area of current or prior skin involvement.
	N_3	Involvement of central lymph nodes.
Viscera	M_0	No evidence of extracutaneous non–lymph node disease.
	M_1	Extracutaneous non–lymph node disease present.

[a] Body regions: head and neck, chest, abdomen/genital, upper back, lower back/buttocks and perineum, upper arms, lower arms/hands, upper legs (thighs), lower legs/feet.
[b] Lymph node regions: a) peripheral sites: antecubital, cervical, supraclavicular, axillary, inguinal-femoral, and popliteal; b) central sites: mediastinal, pulmonary hilar, paraaortic, iliac.

Lymphomatoid Papulosis

LyP is a chronic, recurrent, self-healing skin disease, which mainly affects middle-aged men, with a male-to-female ratio of 2 to 3:1. Its pathogenesis is unclear, but a correlation with a chronic inflammatory status can be hypothesized. No viral correlates have been found in affected skin cells.

Approximately 80% of skin lesions (ranging from 22% to 100%) display clonal TCR rearrangements; however, the presence of a T-cell clone is not required to establish the diagnosis, nor the absence of the clonal rearrangement excludes LyP.

Histological information is required to accomplish the diagnosis, but it needs to be correlated with the overall clinical scenario, given that the morphologic appearance may sometimes closely resemble significantly different diseases.[99,100]

Morphology

LyP has a very heterogeneous appearance upon examination of skin biopsy. For this reason, it has been classified into 6 distinct subtypes, termed A to E, plus a newly recognized subtype harboring the *DUSP22-IRF4* rearrangement. Type A is the most common, accounting for about 75% of the cases, which is characterized by a wedge-shaped dermal infiltrate of large atypical $CD4^+/CD30^+$ lymphocytes within an inflammatory background. Type C, accounting for 10% of the cases, closely resembles type A but it lacks the accompanying inflammatory *pabulum* of neutrophils, eosinophils, and histiocytes. Type B is histologically different, as it is characterized by small $CD4^+/CD8^-/CD30^+$ lymphocytes with cerebriform nuclei and epidermotropism. Importantly, this subtype widely overlaps with the presentation of MF, thus a clinical correlation is always required to establish the correct diagnosis. Type D disease displays epidermotropic infiltrates of small- to medium-sized pleomorphic lymphocytes, usually expressing cytotoxic markers such as granzyme, perforin, and TIA-1. As this subtype largely overlaps with aggressive epidermotropic $CD8^+$ cytotoxic lymphoma, primary cutaneous γ/δ T-cell lymphoma or pagetoid reticulosis in terms of both histology and immunophenotype, it is important to correlate the histologic information with the clinical picture: type D LyP behaves indolently, despite the aggressive appearance upon histology, differently than the aforementioned disease entities which, in contrast, require a more intensive management. Type E shows an angioinvasive infiltrate of atypical lymphocytes in superficial and deep dermis, in a mixed inflammatory background. Histologic and phenotypic peculiarities, however, do not translate into clinically meaningful differences. In other words, the clinical manifestations of the disease are independent of the phenotypic presentation.

Clinical Manifestations

It is a chronic and benign lymphoproliferative disorder, clinically characterized by the presence of papular, papulonecrotic, or nodular skin lesions, mainly affecting the trunk and the extremities. Lesions occur in crops of a few to hundreds, sometimes with long lesion-free intervals. Patients report outbreaks of self-resolving papules, with a relapsing-and-remitting course within 3 to 12 weeks. New lesions may develop while others are regressing. When they coalesce, they may undergo ulceration. Upon disappearance, they leave behind superficial scars or postinflammatory pigmentary changes. The waxing and waning course may last from months to decades before remission; some physiological events—like menses or pregnancy—may modulate the appearance of LyP papules. Transformation into an aggressive lymphoma does not occur; however, in 4% to 25% of the patients, LyP can be associated—or followed by—another malignant lymphoma, such as MF, pcALCL, or Hodgkin disease. For this reason, the onset of persistent lymphadenopathy or systemic symptoms (malaise, fever, weight loss) should prompt the investigation for a systemic lymphoproliferative disease.

Therapy

LyP tends to regress spontaneously, thus no treatment is required. Topical treatments, such as steroids, do not prevent the outbreak of new lesions or disease recurrence; however, they may be useful in relieving associated symptoms, such as pruritus or tenderness. Low-dose methotrexate or PUVA phototherapy may be suitable in case of disseminated disease. BV has an approval for the treatment of LyP, although its exceedingly rarely required. Moreover, given the not negligible risk of peripheral neuropathy correlated with this drug, harm largely outweighs benefit.

Prognosis

The prognosis of LyP is excellent, with a 5-year OS of 100%. For those who develop a secondary overt lymphoma, prognosis overlaps with that of primary disease.

Future Directions

CTCL still remain difficult to manage in cases of advanced-stage disease, as current agents can control the disease temporarily but do not prevent further recurrences or progression. This means that newer agents are needed, and that enrollment in clinical trials is of paramount importance especially of patients with heavily pre-treated disease.

The programmed death-1 (PD-1)- PD-1 ligand (PD-L1) interaction represents a potential target for the treatment of CTCL. Through this interaction, T-cell responses against the tumor are attenuated, thus representing a strategy by which tumors escape to immune surveillance. PD-1 and both its ligands, PD-L1 and PD-L2, are expressed in some hematological malignancies, including MF and SS. In a multicenter phase 2 study, pembrolizumab, a monoclonal antibody which binds to PD-1 receptor inhibiting its interaction with PD-L1 and PD-L2, has demonstrated clinical activity in patients with previously treated MF and SS. Responses were durable and were not associated with any identifiable clinical or pathologic characteristics. Treatment was overall well tolerated, with a toxicity profile consistent with prior pembrolizumab studies, though 40% of patients with SS developed a notable skin flare reaction. The ORR was 38% with 1 CR and 8 PR. Of the responding patients, 6 patients had 90% or greater improvement in skin disease burden.[101]

IPH4102 is a first-in-class humanized IgG_1 monoclonal antibody that binds to KIR3DL2-expressing tumor cells. KIR3DL2 (CD158) is a killer-cell immunoglobulin-like receptor that binds to its cognate HLA-class I ligands negatively modulating immune cell function. This receptor is expressed across most CTCL subtypes. Mechanistically, it recruits human NK cells and macrophages and exerts killing of $KIR3DL2^+$ cells via antibody-dependent cell cytotoxicity and antibody-dependent phagocytosis. A first-in-human, open-label, phase 1 clinical trial with dose-escalation and cohort-expansion parts of IPH4102 enrolled 44 CTCL patients, mostly with SS (80%). Intravenous infusions ranging from 0.0001 mg/kg to 10 mg/kg were assessed. No dose-limiting toxicities were detected in the dose-escalation phase of the trial and the recommended flat dose of 750 mg was considered amenable for the dose-expansion phase of the study. A global ORR of 36.4% was observed; patients affected by SS had an ORR of 43%. Given these promising results, IPH4102 is now being evaluated within phase 2 trials in SS patients and in other subtypes of T-cell lymphomas.[102]

CHAPTER 90

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE AND SMOLDERING MULTIPLE MYELOMA

S. Vincent Rajkumar and Shaji Kumar

Monoclonal gammopathy of undetermined significance (MGUS) is a premalignant clonal plasma cell disorder.[1] It is characterized by the presence of a monoclonal (M) protein in the serum or urine that is commonly discovered during laboratory work-up of a variety disorders. MGUS is a precursor to various hematologic disorders including multiple myeloma (MM), Waldenström macroglobulinemia (WM), solitary plasmacytoma, and immunoglobulin light chain amyloidosis (AL). Smoldering MM (SMM) is a clinically-defined disorder similar to MGUS, but has a much higher risk of progression to MM or a related disorder.[2] SMM is not a unique intermediate biologic stage between MGUS and MM, but it consists of a heterogeneous mixture of patients, some of whom have a biologic premalignancy and have a clinical course resembling MGUS, and some who have an asymptomatic malignancy that will develop end-organ damage typical of MM within a few years. Unfortunately, at the current time, there is no single pathologic or molecular feature that reliably distinguishes patients with SMM who have premalignancy from those with asymptomatic malignancy. MGUS and SMM are usually asymptomatic but can be causally related to a variety of systemic disorders. They also carry a lifelong risk of progression to MM (see Chapter 91) or a related malignancy (see box on Diagnosis of MGUS and SMM: Role of Screening.)

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

MGUS is defined by the presence of a serum monoclonal (M) protein of <3 g/dL (or increased serum free light chain (FLC) level with abnormal free light chain (FLC ratio), $<10\%$ clonal bone marrow plasma cells (BMPC) with no evidence of SMM, end-organ damage, or other myeloma defining events (MDEs) (Table 90.1).[3] There are three major subtypes of MGUS: IgM MGUS, non-IgM MGUS, and light-chain MGUS (LC-MGUS). IgM MGUS carries a risk of progression to WM (see Chapter 92), although patients can rarely develop IgM MM. Non-IgM MGUS is associated with a risk of progression to MM, and LC-MGUS is a precursor of light chain MM. All forms of MGUS can lead to AL amyloidosis (see Chapter 93).

Epidemiology

Prevalence

With conventional testing, MGUS can be detected in approximately 4% of normal persons 50 years of age and older. Age-adjusted rates are greater in men than in women. The prevalence increases with age, exceeding 7.5% among those 85 years or older. Sensitive mass spectrometry studies show that the overall prevalence of MGUS is higher and is estimated at approximately 5% of the general population age 50 years and older.[6] The prevalence of MGUS is higher in Blacks compared to Whites. In a large population-based study ($n = 12{,}482$) of persons 50 years of age and older, using samples from the National Health and Nutrition Examination Survey (NHANES), the adjusted prevalence of MGUS was significantly higher in Blacks (3.7%) compared to Whites (2.3%) or Hispanics (1.8%) ($P < .001$).[7] A subsequent NHANES study found that the racial disparity in prevalence occurs even at younger ages, with MGUS having an onset approximately a decade earlier in Blacks compared with Whites.[8] Table 90.2 gives the estimated prevalence of MGUS by race and age based on NHANES studies.

The increased risk of MGUS seen in African Americans has also been found in Black people living in Ghana. Furthermore, studies show that the racial disparity between Blacks and Whites persists even after adjusting for socio-economic status, suggesting that the disparity in incidence is more likely due to genetics rather than environmental factors. Recent studies show that the t(11;14) translocation type of MGUS may be responsible for most of the increased disparity in MGUS between Blacks and Whites. The probability of having one of three specific subtypes, namely t(11;14), t(14;16), or t(14;20) was significantly higher in the 120 individuals with the highest African ancestry ($\geq 80\%$) compared with the 235 individuals with lowest African ancestry ($<0.1\%$) (51% vs. 33%, respectively, P value $= 0.008$).[9] Studies in other racial groups are limited, but so far an increased risk has not been seen in Japanese individuals, or in Hispanics living in the United States when compared to the White population of Olmsted County.

Incidence

The annual incidence of MGUS in males is estimated to be 120/100,000 at age 50, and rises to 530/100,000 at age 90 years.[10] The rates for women are 60/100,000 at age 50, and 370/100,000 at age 90. When MGUS is first diagnosed, it is estimated that the condition has already been present in an undiagnosed form for a median of over 10 years.

Other Risk Factors

First-degree relatives of patients with MGUS and MM have a two- or threefold higher risk of MGUS compared to those with no known affected relatives.[11] Obesity, exposure to pesticides, and immunosuppression are also known risk factors for MGUS.

DIAGNOSIS OF MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE AND SMOLDERING MULTIPLE MYELOMA: ROLE OF SCREENING

Routine screening is not recommended for MGUS since there are no randomized trials to support such a strategy. There are also no interventions to offer to patients who are diagnosed with MGUS. However, we do not have interventions to prevent end organ damage for patients with high-risk SMM. Since these patients are asymptomatic, diagnosis is incidental. Thus many patients who can potentially benefit from early intervention will go unidentified. This dilemma has led to consideration of screening in high-risk populations, namely Blacks with one affected first-degree relative with MM, and in all others with two or more affected first-degree relatives. In these subsets of the population, the prevalence of MGUS is likely greater than 10%–15%, and the probability of finding patients with high-risk SMM is higher. In our practice, we recommend such selected screening, until we have results of a large, randomized trial in Iceland, which is investigating the role of screening as well as the role of more aggressive follow-up of monoclonal gammopathies.

TABLE 90.1 **International Myeloma Working Group Diagnostic Criteria for Monoclonal Gammopathy of Undetermined Significance, Multiple Myeloma and Related Disorders**

Disorder	Disease Definition
IgM monoclonal gammopathy of undetermined significance (IgM MGUS)	All three criteria must be met: • Serum IgM monoclonal protein <3 g/dL • Bone marrow lymphoplasmacytic infiltration <10% • No evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder
Non-IgM monoclonal gammopathy of undetermined significance (MGUS)	All three criteria must be met: • Serum monoclonal protein (non-IgM type) <3 g/dL • Clonal bone marrow plasma cells <10%[a] • Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, and bone lesions (CRAB) that can be attributed to the plasma cell proliferative disorder
Light chain MGUS	All criteria must be met: • Abnormal FLC ratio (<0.26 or >1.65) • Increased level of the appropriate involved light chain (increased kappa free light chain (FLC) in patients with ratio >1.65 and increased lambda FLC in patients with ratio <0.26) • No immunoglobulin heavy chain expression on immunofixation • Absence of end-organ damage that can be attributed to the plasma cell proliferative disorder • Clonal bone marrow plasma cells <10% • Urinary monoclonal protein <500 mg/24 h
Smoldering multiple myeloma	Both criteria must be met: • Serum monoclonal protein (IgG or IgA) ≥3 g/dL, or urinary monoclonal protein ≥500 mg/24 h and/or clonal bone marrow plasma cells 10%–60% • Absence of myeloma defining events or amyloidosis

Multiple myeloma	Both criteria must be met:
	• Clonal bone marrow plasma cells ≥10% or biopsy-proven bony or extramedullary plasmacytoma
	• Any one or more of the following myeloma defining events:
	  • Evidence of end organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically:
	  • Hypercalcemia: serum calcium >0·25 mmol/L (>1 mg/dL) higher than the upper limit of normal or >2·75 mmol/L (>11 mg/dL)
	  • Renal insufficiency: creatinine clearance <40 mL per minute or serum creatinine >177 µmol/L (>2 mg/dL)
	  • Anemia: hemoglobin value of >2 g/dL below the lower limit of normal, or a hemoglobin value <10 g/dL
	  • Bone lesions: one or more osteolytic lesions on skeletal radiography, computed tomograph (CT), or positron emission tomography-CT (PET-CT)
	• Clonal bone marrow plasma cell percentage ≥60%
	• Involved:uninvolved serum FLC ratio ≥100 (involved FLC level must be ≥100 mg/L)
	• >1 focal lesions on magnetic resonance imaging (MRI) studies (at least 5 mm in size)

Smoldering Waldenström macroglobulinemia (also referred to as indolent or asymptomatic Waldenström's macroglobulinemia)	Both criteria must be met: • Serum IgM monoclonal protein ≥3 g/dL and/or bone marrow lymphoplasmacytic infiltration ≥10% • No evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder.
Waldenström macroglobulinemia	All criteria must be met: • IgM monoclonal gammopathy (regardless of the size of the M protein) • ≥10% bone marrow lymphoplasmacytic infiltration (usually intertrabecular) by small lymphocytes that exhibit plasmacytoid or plasma cell differentiation and a typical immunophenotype (e.g., surface IgM^{+}, $CD5^{+/-}$, $CD10^{-}$, $CD19^{+}$, $CD20^{+}$, $CD23^{-}$) that satisfactorily excludes other lymphoproliferative disorders including chronic lymphocytic leukemia and mantle cell lymphoma • Evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder
Solitary plasmacytoma	All 4 criteria must be met • Biopsy proven solitary lesion of bone or soft tissue with evidence of clonal plasma cells • Normal bone marrow with no evidence of clonal plasma cells • Normal skeletal survey and MRI (or CT) of spine and pelvis (except for the primary solitary lesion) • Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, or bone lesions (CRAB) that can be attributed to a lympho-plasma cell proliferative disorder
Solitary plasmacytoma with minimal marrow involvement[b]	All four criteria must be met • Biopsy proven solitary lesion of bone or soft tissue with evidence of clonal plasma cells • Clonal bone marrow plasma cells <10% • Normal skeletal survey and MRI (or CT) of spine and pelvis (except for the primary solitary lesion) • Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, or bone lesions (CRAB) that can be attributed to a lympho-plasma cell proliferative disorder

Continued

TABLE 90.1 International Myeloma Working Group Diagnostic Criteria for Monoclonal Gammopathy of Undetermined Significance, Multiple Myeloma and Related Disorders—cont'd

Disorder	Disease Definition
Systemic AL amyloidosis	All four criteria must be met: • Presence of an amyloid-related systemic syndrome (such as renal, liver, heart, gastrointestinal tract, or peripheral nerve involvement) • Positive amyloid staining by Congo red in any tissue (e.g., fat aspirate, bone marrow, or organ biopsy) • Evidence that amyloid is light-chain related established by direct examination of the amyloid using mass spectrometry (MS)-based proteomic analysis, or immuno-electron microscopy • Evidence of a monoclonal plasma cell proliferative disorder (serum or urine M protein, abnormal FLC ratio, or clonal plasma cells in the bone marrow) **Note:** Approximately 2%–3% of patients with AL amyloidosis will not meet the requirement for evidence of a monoclonal plasma cell disorder listed above; the diagnosis of AL amyloidosis must be made with caution in these patients. Patients with AL amyloidosis who also meet criteria for multiple myeloma are considered to have both diseases.
POEMS syndrome	All four criteria must be met • Polyneuropathy • Monoclonal plasma cell proliferative disorder (almost always lambda) • Any one of the following three other major criteria: 1 Sclerotic bone lesions 2 Castleman's disease 3 Elevated levels of vascular endothelial growth factor (VEGF)[†] • Any one of the following six minor criteria 1 Organomegaly (splenomegaly, hepatomegaly, or lymphadenopathy) 2 Extravascular volume overload (edema, pleural effusion, or ascites) 3 Endocrinopathy (adrenal, thyroid, pituitary, gonadal, parathyroid, pancreatic)[‡] 4 Skin changes (hyperpigmentation, hypertrichosis, glomeruloid hemangiomata, plethora, acrocyanosis, flushing, white nails) 5 Papilledema 6 Thrombocytosis/polycythemia **Note:** Not every patient meeting the above criteria will have POEMS syndrome; the features should have a temporal relationship to each other and no other attributable cause. Anemia and/or thrombocytopenia are distinctively unusual in this syndrome unless Castleman disease is present. [†]The source data do not define an optimal cut off value for considering elevated VEGF level as a major criterion. We suggest that VEGF measured in the serum or plasma should be at least three- to fourfold higher than the normal reference range for the laboratory that is doing the testing to be considered a major criterion. [‡]In order to consider endocrinopathy as a minor criterion, an endocrine disorder other than diabetes or hypothyroidism is required since these two disorders are common in the general population.

[a] A bone marrow can be deferred in patients with low-risk MGUS (IgG type, M protein <15 g/L, normal free light chain ratio) in whom there are no clinical features concerning for myeloma.

[b] Solitary plasmacytoma with 10% or more clonal plasma cells is considered as multiple myeloma.

Modified from Landgren O, Graubard BI, Kumar S, et al. Prevalence of myeloma precursor state monoclonal gammopathy of undetermined significance in 12372 individuals 10–49 years old: a population-based study from the National Health and Nutrition Examination Survey. *Blood Cancer J.* 2017;7:e618.

Pathobiology

MGUS likely originates when plasma cells are dividing in response to antigenic stimulation. During this period of antigenic stimulation they acquire a primary cytogenetic abnormality that established the MGUS clone (Fig. 90.1).[12] The primary cytogenetic abnormalities associated with the onset of MGUS consist of two major types: trisomies and immunoglobulin heavy chain (IgH) translocations (Table 90.3). IgH translocations involve the immunoglobulin heavy chain switch region on chromosome 14q32, and one of five common partner chromosomes loci: 11q13 (CCND1 [cyclin D1 gene]), 4p16.3 (FGFR-3 and MMSET), 6p21 (CCND3 [cyclin D3 gene]), 16q23 (c-MAF), and 20q11 (MAF-B).

MGUS may stay dormant or acquire secondary cytogenetic abnormalities and progress to MM or a related malignancy. The rate of progression of MGUS is approximately 1% per year regardless of the known duration of antecedent MGUS, indicating a random hit model of progression.[13] Although the precise pathogenetic steps are unclear, there appear to be two main pathways involved, namely, *MYC* translocations and mutations in the MAP kinase pathway. The presence of *MYC* structural variants is associated with a significantly shorter median time to progression (TTP) compared to the absence of such abnormalities. Other abnormalities associated with progression include chromosome 1q21 (gain 1q), p16 methylation, p53 mutations, and changes in the bone marrow microenvironment, including induction of angiogenesis and suppression of cell-mediated immunity, affecting things such as T-cell production.

Progression is also associated with increase in receptor activator of nuclear factor κB ligand (RANKL) expression by osteoblasts and possibly plasma cells accompanied by decreased stromal cell secretion of the RANKL decoy receptor, osteoprotegerin (OPG). There is also release of macrophage inflammatory protein–1α (MIP-1α) and MIP-1β by myeloma cells. Collectively these changes promote osteoclast activation through the nuclear factor κB (NF-κB) pathway. In addition, there is simultaneous inhibition of osteoblasts mediated by increased dickkopf 1 (DKK-1) expression by myeloma cells. The combination of osteoclast activation and inhibition of osteoblast differentiation is thought to be the mechanism behind the development of osteolytic lesions in MM, and may also explain increased risk of fractures seen in MGUS even in absence of progression to MM.

Clinical Manifestations

MGUS is an asymptomatic condition.[14] It is typically detected as an incidental finding when electrophoresis and immunofixation of the serum and/or urine, or the serum FLC assay are performed during the work-up of suspected MM or WM, including symptoms such as unexplained weakness or fatigue, increased erythrocyte sedimentation rate, anemia, unexplained back pain, osteoporosis, osteolytic lesions or fractures, hypercalcemia, proteinuria, renal insufficiency, or recurrent infections. MGUS may also be detected during work-up of patients with symptoms suggestive of AL amyloidosis such as unexplained sensorimotor peripheral neuropathy, carpal tunnel syndrome, refractory congestive heart failure, nephrotic syndrome, orthostatic hypotension, malabsorption, weight loss, change in the tongue or voice, paresthesias, numbness, increased bruising, bleeding, and steatorrhea.

Association of Monoclonal Gammopathy of Undetermined Significance With Other Diseases

Although most patients diagnosed with MGUS are asymptomatic, some can have disorders that are causally related to the M protein, without any evidence of overt progression to MM or related malignancy (Table 90.4).[14] In fact, increasingly MGUS is diagnosed in such situations, during work-up of unexplained renal, neuropathic, or other organ dysfunction. Over a hundred different medical conditions have been reported to be associated with MGUS, but most such reported associations are coincidental rather than causal. The important causal related disorders are discussed below.

Monoclonal Gammopathy Associated Neuropathy

Approximately 3% to 5% of patients with monoclonal gammopathy have a peripheral neuropathy, and approximately 3% to 5% of patients with a peripheral neuropathy have evidence of an M protein. IgM MGUS associated neuropathy presents as a chronic

Other IgH translocations	The genes affected vary depending on the partner chromosome

[a] Other rare partner chromosomes have been described. Some patients have combined IgH translocations and trisomies, but they should be classified based on the IgH translocation.

distal, acquired, demyelinating, symmetric sensory neuropathy (DADS-M).[15] In approximately half of these patients, the IgM M protein binds to myelin-associated glycoprotein (MAG). In contrast, patients with non-IgM associated neuropathy have a varied presentation, but the clearest association is in patients who present with features similar to chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) with predominantly motor involvement with distal and proximal involvement. MGUS neuropathy must be differentiated from two other plasma cell disorders that cause neuropathy that have been well characterized and have strict diagnostic criteria, namely immunoglobulin light chain (AL) amyloidosis, and neuropathy associated with POEMS (polyneuropathy, organomegaly).

Monoclonal Gammopathy Associated Renal Disorders

A substantial proportion of cases with "idiopathic" immune-complex mediated membranoproliferative glomerulonephritis (MPGN) are now felt to be related to MGUS.[16] MGUS can cause proliferative glomerulonephritis by direct deposition of M protein in the mesangium and along capillary walls, resulting in an immune complex-mediated proliferative glomerulonephritis. It can also cause glomerulonephritis by, indirectly, activating the alternative pathway of complement resulting in deposition of complement factors in the glomeruli, resulting in C3 glomerulopathy. The term monoclonal gammopathy of renal significance (MGRS) is used to describe renal diseases such as those caused by a premalignant MGUS clone, and the aforementioned M protein-related disorders such as AL amyloidosis and monoclonal immunoglobulin deposition disease.

Monoclonal Gammopathy Associated Dermatologic Diseases

A variety of dermatologic diseases have been associated with MGUS including lichen myxedematosus (papular mucinosis, scleromyxedema), scleredema (Buschke disease), pyoderma gangrenosum, diffuse plane xanthomatosis, and subcorneal pustular dermatosis. Other skin disorders associated with MGUS are necrobiotic xanthogranuloma and Schnitzler syndrome, a rare disorder characterized by chronic urticaria and an IgM monoclonal gammopathy.

Other Associations of Monoclonal Gammopathy of Undetermined Significance

MGUS has been associated with an increased risk of fractures and deep vein thrombosis, and has been linked to chronic lymphocytic leukemia, hairy cell leukemia, T-cell lymphoma, and other malignancies, but the significance of these associations is not known. MGUS has also been associated with acquired von Willebrand disease, Gaucher disease, pure red cell aplasia, connective tissue disorders, various neurologic disorders. and can occasionally be the cause of systemic capillary leak syndrome.

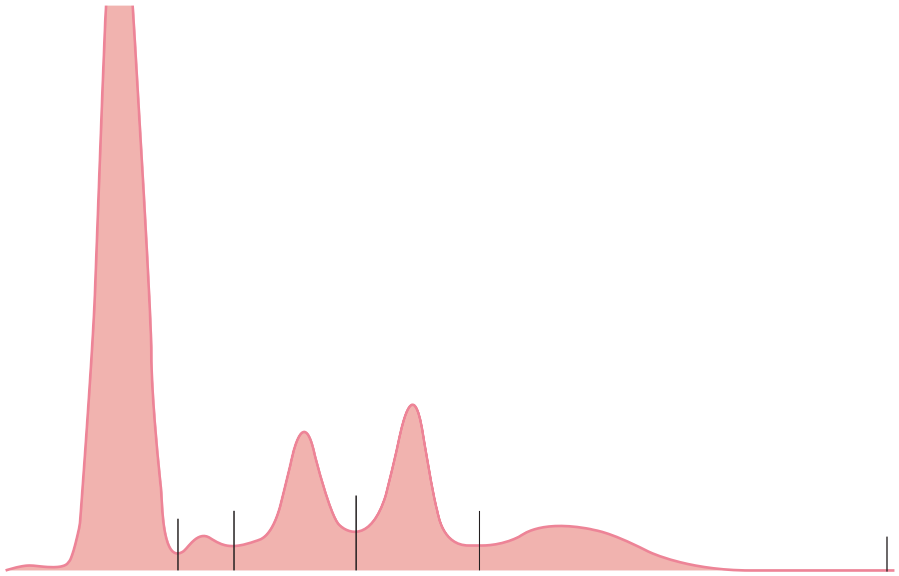
TABLE 90.4 **Non-Malignant Diseases Associated With Monoclonal Gammopathy of Undetermined Significance and May Respond to Lymphoplasmacytic Cell-Directed Therapy**

Primary Organ Involved	Clinical Presentation	Role of Monoclonal Protein/ Pathophysiology
Schnitzler syndrome	Chronic urticaria, fever, bone pain, IgM-MGUS	Unclear
Insulin autoimmune syndrome	Episodic confusion, diaphoresis, dizziness, lethargy, palpitation, seizure	Antibody to insulin causing its inactivation
TEMPI	Telangiectasias, erythrocytosis, elevated erythropoietin level, MGUS, perinephric fluid collections, and intrapulmonary shunting	Unclear
Rheumatologic scleromyxedema	Waxy papules or plaques, arthralgia, restrictive lung disease, seizure	Unclear
Progressive glomerulonephritis with monoclonal immunoglobulin deposits	Hematuria, hypertension, proteinuria, renal impairment, mostly IgG3κ-MGUS	Granular deposition of immunoglobulin in glomeruli
Sporadic late-onset nemaline myopathy	Muscular weakness and atrophy frequently resulting in "head drop," respiratory insufficiency, congestive heart failure	Unclear
Crystalline keratopathy	Decreased visual acuity, corneal opacity, IgGκ-MGUS	Corneal deposition of antibody forming a crystalline structure
Crystal-storing histiocytosis	Mass or tissue infiltration, which may involve the bone marrow, breast, gastrointestinal tract, kidneys, lymph node, skin, or spleen	Accumulation of light chain crystals in histiocytes

MGUS, Monoclonal gammopathy of undetermined significance.
From Go RS, Rajkumar SV. How I manage monoclonal gammopathy of undetermined significance. *Blood*. 2018;131;163–173. © American Society of Hematology.

Laboratory Manifestations

The hallmark of MGUS is the presence of an M protein in the serum and/or urine. M proteins are detected using protein electrophoresis of the serum and urine. The M protein appears as a narrow peak (like a church spire) on the densitometer tracing or as a dense, discrete band on agarose gel (Fig. 90.2). Protein electrophoresis also permits quantitation of M proteins. Urine electrophoresis requires a 24-hour urine collection. Immunofixation of the serum and urine is more sensitive than protein electrophoresis and is used to identify the type of M protein heavy and light chains (IgM kappa, IgG lambda, etc.).



Fraction	%	Units

The FLC assay is a nephelometric assay that measures free kappa (κ) and lambda (λ) light chains that are not bound to intact immunoglobulin. Patients with abnormally low kappa/lambda FLC ratios are considered to have a monoclonal lambda FLC, and those with abnormally high ratios are defined as having a monoclonal kappa FLC. The serum FLC assay is more sensitive than electrophoresis or immunofixation in detecting free monoclonal light chains, and must be done at diagnosis in conjunction with those tests.

At diagnosis, osteolytic bone disease must be excluded in order to distinguish MGUS from MM. The preferred method to detect bone disease is a whole-body low-dose computed tomography (CT).[17] Positron emission tomography-CT (PET-CT) is an equally sensitive alternative to whole body low-dose CT. A unilateral bone marrow aspiration and biopsy, if indicated, must show less than 10% clonal BMPCs. For flow cytometry, plasma cells in MGUS typically stain positive for CD38 and CD138, and are positive only for one of the two light chain isotypes, indicating they are monoclonal (either kappa or lambda). Baseline cytogenetic abnormalities are best ascertained by fluorescent in situ hybridization (FISH) testing on the bone marrow sample at diagnosis (Fig. 90.3). In patients suspected of monoclonal protein related disorders, confirmatory testing is needed, such as renal biopsy in patients with monoclonal gammopathy associated proliferative glomerulonephritis (Fig. 90.4).

Differential Diagnosis

MGUS is differentiated from MM and SMM by the size of the M protein, the BMPC percentage, and the presence or absence of anemia, renal failure, hypercalcemia, or lytic bone lesions (see Table 90.1). Because anemia and renal insufficiency are relatively common in the elderly population with MGUS, the causes of these conditions should be carefully investigated with adequate laboratory studies.

Prognosis

MGUS is associated with a life-long risk of progression to MM or a related disorder. In a study of 1384 patients from Southeastern Minnesota, the risk of progression of MGUS to MM or related malignancy was 1% per year.[13] The true life-time probability of progression is lower when competing causes of death are taken into account, approximately 11% at 25 years.[18] The risk of progression with MGUS does not diminish with time, even after over 30 years of follow-up.[1] Progression events include MM, WM, solitary plasmacytoma, and AL amyloidosis. The risk of progression from MGUS has been estimated in several other studies, and the results mirror those seen in the Southeastern Minnesota study. No findings from the diagnosis of MGUS can reliably distinguish patients whose condition will remain stable indefinitely from those in whom MM or related malignancy develops. However, there are several known prognostic factors that assist in estimation of the risk of progression for appropriate counseling and management.

Size of M Protein

The size of the M protein at recognition of MGUS is one of the most important predictors for the risk of progression. In the study of 1384 patients from Southeastern Minnesota, the risk of progression to MM or a related disorder 10 years after diagnosis of MGUS was 6% for patients with an initial M-protein level of 0.5 g/dL or less, 7% for 1 g/dL, 11% for 1.5 g/dL, 20% for 2 g/dL, 24% for 2.5 g/dL, and 34% for 3.0 g/dL.[13]

Type of M Protein

Patients with an IgM or IgA M protein have a higher risk of progression compared with those with an IgG M protein.[13] IgM MGUS is a unique subtype of MGUS in which patients are at risk of progression to WM rather than MM. Rarely patients with IgM MGUS can evolve into IgM MM.

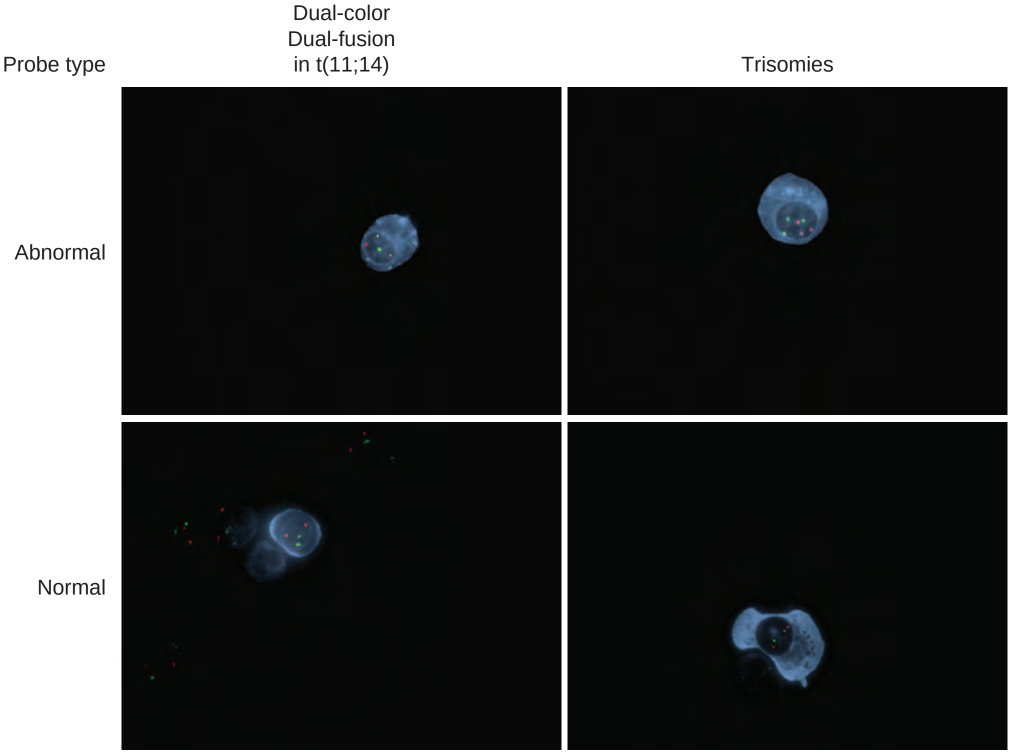

Figure 90.3 FLUORESCENT IN SITU HYBRIDIZATION (FISH). Cytoplasmic immunoglobulin (cIg) stain antibodies for kappa and lambda are used to detect plasma cells in unsorted bone marrow. Representative FISH images of cIg-positive plasma cells using the following probes: CCND1/IGH (CCND1-XT[11q13](R)/IGH-XT[14q32](G), Abbott Molecular) to detect t(11;14)(q13;q32); D3Z1/D7Z1 (D3Z1[CEN3](R)/D7Z1[CEN7](G), Abbott Molecular) for trisomy 3 and/or 7 (G = green, R = red). Abnormal (*top from left to right*): showing representative patients with a t(11;14) translocation showing a fusion signal (yellow), and trisomies 3 and 7 (three red and three green signals seen instead of two each). Normal (*bottom from left to right*): representative patient with a normal signal pattern for the listed probes. *(Images provided by the Mayo Clinic Genomics Laboratory.)*

(B–E) Immunofluorescence studies showing granular (B) IgG, (C) C3, (D) kappa light chains along capillary walls, and (E) negative lambda light chains. (F) Electron microscopy showed sub-endothelial electron dense deposits *(arrows)*.

Abnormal Serum-Free Light Chain Ratio

An abnormal FLC ratio is an independent risk factor for progression of MGUS, and is present in approximately one-third of patients with MGUS.[18] The risk of progression in patients with an abnormal FLC ratio was significantly higher than that in patients with a normal ratio (hazard ratio 3.5; $P < .001$).

Other Risk Factors

Patients with MGUS with 5% to 9% BMPCs had a higher risk of progression than those with <5% BMPCs. The risk of progression of MGUS is also increased if there is associated suppression of the other uninvolved immunoglobulins.

Risk Stratification

A risk-stratification model, based on the size and type of the M protein and the FLC ratio, is used to predict risk of progression of MGUS (Table 90.5).[18] Patients with all three risk factors consisting of an abnormal serum FLC ratio, IgA or IgM MGUS, and an increased serum M-protein value (≥1.5 g/dL) have a risk of progression at 20 years of 58%, whereas the risk is 5% when none of the risk factors are present.

TABLE 90.5 **Risk-Stratification Model to Predict Progression of Monoclonal Gammopathy of Undetermined Significance to Myeloma or Related Disorders**

Risk Group	No. of Patients	Relative Risk	Absolute Risk of Progression at 20 Years	Absolute Risk of Progression at 20 Years Accounting for Death as a Competing Risk
Low-risk (Serum M protein <1.5 g/dL, IgG subtype, normal FLC ratio (0.26–1.65)	449	1	5%	2%
Low-intermediate-risk (Any 1 factor abnormal)	420	5.4	21%	10%
High-intermediate-risk (Any 2 factors abnormal)	226	10.1	37%	18%
High-risk (All 3 factors abnormal)	53	20.8	58%	27%

From Rajkumar SV, Kyle RA, Therneau TM, et al. Serum free light chain ratio is an independent risk factor for progression in monoclonal gammopathy of undetermined significance. *Blood*. 2005; 106;812–817. © American Society of Hematology.

Life Expectancy

In a population-based study of 1384 patients with MGUS in Southeastern Minnesota, a lower survival was seen compared to age-matched control population, even after excluding all persons who progressed to MM or related disorders.[1] However, it is not clear whether the excess risk of death from MGUS was due to the conditions that led to testing for MGUS, or whether there is a true adverse impact on survival that is independent of malignant progression.

Therapy

The approach to management of MGUS is given in Fig. 90.5. All patients diagnosed with MGUS need baseline complete blood count (CBC), serum calcium, and serum creatinine. If available, peripheral blood flow cytometry for circulating plasma cells should also be done. Radiographic studies of the bones can be omitted in asymptomatic patients with IgM MGUS or low-risk MGUS (see Table 90.5). A bone marrow biopsy can be deferred in patients with a clinical picture otherwise consistent with MGUS, and the patient is classified as low-risk MGUS based on the risk-stratification model shown in

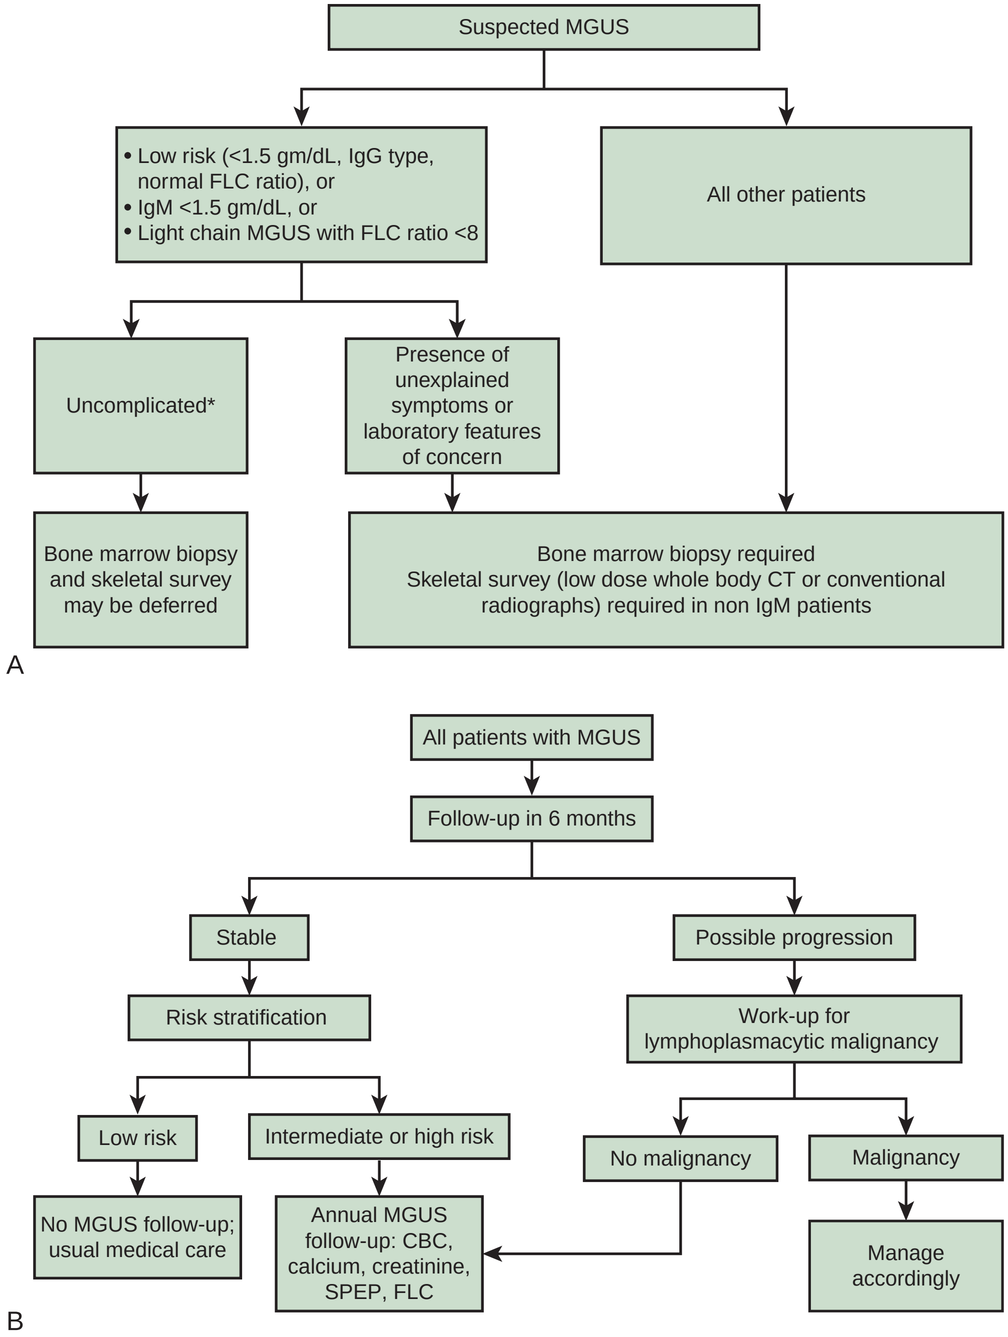
Table 90.5.[14] A bone marrow biopsy can also be deferred in patients with a small (<1.5 g/dL) IgM MGUS and normal blood counts.

No therapy is needed for MGUS. In all patients, the CBC, serum calcium, creatinine and serum protein electrophoresis, and serum FLC must be repeated in 6 months. If stable, further follow-up can be deferred in patients with low-risk MGUS until worrisome symptoms for progression develop. In all other patients with MGUS, lifelong annual follow-up of the M protein is recommended (see box on Approach to Monoclonal Gammopathy of Undetermined Significance).

Clinical trials are ongoing to determine if the risk of progression can be reduced by low-risk interventional approaches. However, since the overall risk of progression is low, any intervention will have to be highly effective with very low risk to justify incorporation into clinical practice. A promising clinical trial in Iceland is testing if more aggressive monitoring can detect MM early in patients with MGUS, and can provide clinical benefit.

MGUS Associated Disorders

The results of treatment of peripheral neuropathy and monoclonal gammopathy have been disappointing. For patients with IgM monoclonal gammopathy associated neuropathy, a trial of intravenous immunoglobulin (IVIG) is reasonable.[15] Rituximab can be considered if IVIG is not of benefit. If patients are refractory to rituximab, or other treatments used for WM can be tried on a case-by-case basis. For patients with non-IgM monoclonal gammopathy associated neuropathy who present similar to CIDP, therapy should



Suspected MGUS
• Low risk (<1.5 gm/dL, IgG type, normal FLC ratio), or

How I manage monoclonal gammopathy of undetermined significance. Blood. 2018;131(2):163–173. © American Society of Hematology.)*

APPROACH TO MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

The first step in the evaluation of MGUS is to exclude multiple myeloma, AL amyloidosis, or related malignancy. At the same time, even if anemia, hypercalcemia, or renal failure was present, a diagnosis of myeloma cannot be assumed. Other causes need to be excluded. In patients with uncomplicated low-risk MGUS by risk stratification (see Table 90.5), we usually omit both the bone marrow biopsy and bone imaging. A repeat measurement of the M protein in 6 months is sufficient. A bone marrow biopsy can also be omitted in small (<1.5 g/dL) IgM MGUS. Further patients with IgM MGUS of any size do not need bone imaging unless they have concerning symptoms. This strategy reduces the number of unnecessary investigations and reduces cost. The yield of these procedures in such patients has been shown to be extremely low. All other patients need a baseline bone marrow biopsy and bone imaging.

be similar to that used for the treatment of classic CIDP with plasmapheresis, IVIG, and steroids. Patients with monoclonal gammopathy associated glomerulonephritis may benefit from attempts to lower or eradicate the M protein, with treatments used in MM such as bortezomib, cyclophosphamide, dexamethasone (VCd), or daratumumab.[16]

VARIANTS OF MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Secondary Monoclonal Gammopathy of Undetermined Significance

Secondary MGUS refers to new M proteins that arise in myeloma patients following therapy that is of an isotype distinct from the original clone. In a study of 1942 patients with MM, 128 (6.6%) developed a secondary MGUS, at a median time of 12 months from the diagnosis of MM.[19] Secondary MGUS is usually transient and disappears at a median duration of 6 months. In some, there can be multiple secondary MGUS's of varying isotypes. Secondary MGUS occurs more commonly following stem cell transplantation, and most of these M proteins are small and detectable by immunofixation only. Interestingly, overall survival of MM is significantly superior among patients who developed secondary MGUS compared with those who do not, especially if the M protein resolves over time.

Biclonal and Triclonal Gammopathy

Occasionally two or three unique M proteins can be detected in one person at the same time and are referred to as biclonal and triclonal gammopathies. In some patients complete class switching in a single plasma cell clone results in the production of two M proteins, but in others, two or more M proteins can arise from separate plasma cell clones.

SMOLDERING MULTIPLE MYELOMA

Introduction

SMM is defined by the presence of a serum M protein of ≥ 3 g/dL (or urine M protein ≥ 500 mg/24 h), and/or 10% to 60% clonal BMPC with no evidence of end-organ damage (i.e., CRAB criteria), or other MDE (see Table 90.1).[3] It is distinguished from MGUS based on the level of serum M protein and the percentage of clonal BMPCs.[2] The current International Myeloma Working Group (IMWG) diagnostic criteria for SMM excludes patients with clonal BMPC $\geq$ 60%, serum involved/uninvolved FLC ratio of ≥ 100, and those with two or more focal bone lesions on magnetic resonance imaging (MRI).[3] Such patients have an approximately 80% risk of progression to end-organ damage and are considered as MM. Light chain SMM is a unique subtype of SMM in which there is monoclonal FLC excess with no expression of IgH.[20] This entity is characterized by excess secretion (≥ 500 mg/24 hours) of monoclonal FLC in the urine (Bence Jones proteinuria).

Epidemiology

SMM accounts for approximately 15% of all cases of newly diagnosed MM. An estimate of the true prevalence of SMM on the basis of updated IMWG criteria is not available. Furthermore, since SMM is asymptomatic and requires bone marrow examination for diagnosis, prevalence in the general population is unknown. Details on racial disparity are not available, but it is likely that as with MGUS and MM, the prevalence of SMM is likely to be two- to threefold higher in Blacks compared to Whites.

Pathobiology

SMM is not a unique biologic entity. It is a heterogeneous entity created primarily for clinical purposes to identify a group of patients with an asymptomatic plasma cell dyscrasia, who have a much higher risk of progression than MGUS, so that they can be monitored more closely.[3] SMM includes patients with premalignancy (biological MGUS), as well as patients with early asymptomatic malignancy (MM) who will develop clinical symptoms and end-organ damage within a few years. Unfortunately, at present, histopathologic and other laboratory methods cannot distinguish SMM patients with premalignant MGUS from those who have early MM, since there is no clear marker of malignancy that can distinguish a clonal premalignant plasma cell from a clonal malignant MM cell.

Clinical Manifestations

As with MGUS, SMM is asymptomatic and is diagnosed during the routine work-up for a variety of symptoms and signs. In some patients SMM may be diagnosed in conjunction with one of the monoclonal gammopathy associated disorders that are listed in Table 90.4. Unlike MGUS, which has a low 1% per year risk of progression, most patients with SMM progress eventually to MM or related disorder. Therefore, the distinction between MGUS and SMM has major implications for baseline testing, follow-up, and consideration for clinical trials.

Laboratory Manifestations

The diagnostic work-up of suspected SMM should include CBC, biochemical studies including creatinine and calcium, albumin, serum FLCs, and quantitative immunoglobulins in addition to protein electrophoresis and immunofixation of the serum and urine. Any abnormality that is detected on CBC or chemistry examination must have an alternative explanation, and must be felt to be unrelated to the underlying clonal plasma cell disorder. Bone imaging is mandatory, and should show no evidence of osteolytic lesions. Whole body CT imaging is more sensitive for the detection of bone disease compared to whole body X-ray.[17] Low-dose whole body CT can detect osteolytic lesions in approximately 20% of patients with negative skeletal surveys. Bone marrow examination is required, and by definition should reveal 10% to 60% clonal plasma cells (Fig. 90.6). Bone marrow FISH studies must be done to ascertain the primary cytogenetic subtype of SMM which has prognostic significance. The primary cytogenetic classification of SMM is the same as MGUS (and MM), as shown on Table 90.3. BMPC immunophenotyping by multiparametric flow cytometry is needed to enable accurate risk stratification.

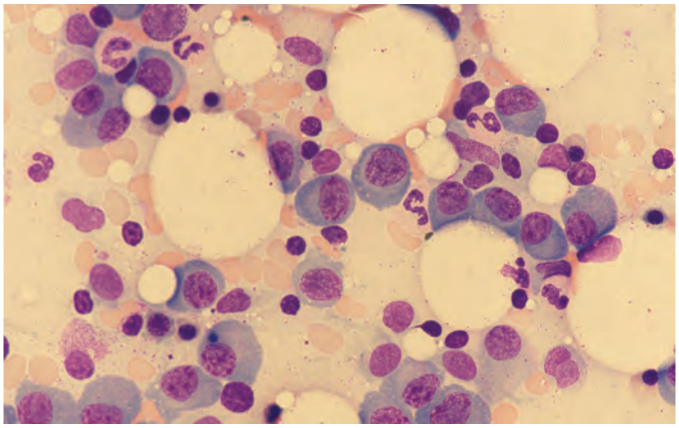

Figure 90.6 BONE MARROW ASPIRATE. Bone marrow aspirate at 600× magnification showing increased plasma cells in smoldering multiple myeloma.

If after the above work-up SMM is considered as the likely diagnosis, additional imaging with whole body MRI is needed to definitively exclude MM. By IMWG diagnostic criteria, patients with >1 focal lesion on MRI are now categorized as having MM. However, whole body MRI is not available in all practice settings. In a study that compares spine and pelvis MRIs to a whole-body MRI in MGUS patients, 90% of lesions were detected by MRI of the spine and pelvis, making this a reasonable alternative. PET-CT for evaluation of SMM is recommended by the IMWG in the event whole body MRI is not available.[17]

Differential Diagnosis

SMM must be distinguished from MGUS, MM, AL amyloidosis, and other related disorders using the criteria listed in Table 90.1. Patients with SMM must then be risk stratified into low-, intermediate-, and high-risk SMM based on the criteria discussed below (Table 90.6).

Prognosis

The risk of progression in SMM is 10% per year, compared to 1% per year in MGUS.[21] The risk of progression is affected by a number of variables, which essentially help identify the subset of SMM patients who have asymptomatic malignancy (high-risk SMM) from those with biologic MGUS (low-risk SMM). No one variable is adequate. However, by combining variables, we can get a reasonably accurate identification of patients with high-risk SMM who are candidates for early intervention and clinical trials.

Size and Type of M Protein

The size and type of the serum M protein are significant risk factors for progression in SMM.[21] The TTP is significantly shorter in patients with IgA M protein compared with IgG M protein, median 27 months versus 75 months, respectively, *P* = .004. The risk of progression in light-chain SMM is lower, with median TTP of approximately 160 months in one study.

Extent of Bone Marrow Involvement

Even after IMWG diagnostic criteria were updated to reclassify patients with ≥60% clonal BMPCs as having MM, the risk of progression in SMM is still influenced by the extent of bone marrow involvement. In a Mayo Clinic study, median TTP was 117 months for patients with <20% BMPCs versus 26 months for patients with 20% to 50% bone marrow involvement, *P* < .001.[21] BMPC estimates should be done on either the bone marrow aspirate or biopsy examination, and in the event of a discrepancy the higher of the two values should be used.[3] BMPC estimates must not be estimated from flow cytometry or from immunostaining.

TABLE 90.6 Definition of High-Risk Smoldering Multiple Myeloma[a]

Bone marrow clonal plasma cells ≥10% and any one or more of the following:
Serum M protein ≥30 g/L
IgA SMM
Immunoparesis with reduction of two uninvolved immunoglobulin isotypes
Serum involved/uninvolved free light chain ratio ≥8 (but <100)
Progressive increase in M protein level (Evolving type of SMM)[b]
Bone marrow clonal plasma cells 50%–60%
Abnormal plasma cell immunophenotype (≥95% of bone marrow plasma cells are clonal) and reduction of one or more uninvolved immunoglobulin isotypes
t (4;14) or del 17p or 1q gain
Increased circulating plasma cells
MRI with diffuse abnormalities or 1 focal lesion
PET-CT with focal lesion with increased uptake without underlying osteolytic bone destruction

[a] Note that the term smoldering multiple myeloma excludes patients without end-organ damage who meet revised definition of multiple myeloma, namely clonal bone marrow plasma cells ≥60% or serum free light chain (FLC) ratio ≥100 (plus measurable involved FLC level ≥100 mg/L), or more than one focal lesion on magnetic resonance imaging. The risk factors listed in this table are not meant to be indications for therapy; they are variables associated with a high risk of progression of SMM, and identify patients who need close follow-up and consideration for clinical trials.

[b] Increase in serum monoclonal protein by ≥25% on two successive evaluations within a 6 month period*M*, Monoclonal; *MRI*, magnetic resonance imaging; *PET-CT*, positron emission tomography-computed tomography; *SMM*, smoldering multiple myeloma.

From Rajkumar SV, Landgren O, Mateos MV. Smoldering multiple myeloma. *Blood*. 2015;125:3069–75. © American Society of Hematology.

Suppression of Uninvolved Immunoglobulins

In one study, median TTP was 159 months in patients with normal levels of uninvolved immunoglobulins, 89 months in those with a reduction in one isotype, and 32 months in patients with reduction in two isotypes of uninvolved immunoglobulins, *P* = .001.[21] Other studies have confirmed these results.

Magnetic Resonance Imaging

Patients with one focal lesion and those with solely diffuse (non-focal) abnormalities on MRI are at increased risk of progression to MM, and require more frequent follow-ups and repeat imaging in 3 to 6 months.[22] Patients with two or more focal lesions are considered to have MM.

Positron Emission Tomography-Computed Tomography

The finding of an increased uptake on PET-CT without bone destruction is not adequate to be considered as a MDE. The patients with the absence of other MDEs should be considered to have high-risk SMM. Zamagni and colleagues studied 120 SMM patients who had undergone PET-CT imaging, to assess the impact of increased uptake without underlying osteolysis.[23] They found increased PET-CT uptake without evidence of osteolysis in 16% of patients. The median TTP was significantly shorter for patients with increased PET-CT uptake compared to patients with negative PET-CT, median TTP 1.1 versus 4.5 years, *P* = .001. The probability of progression within 2 years was 58% for PET-CT positive versus the 33% for PET-CT negative patients.

Serum Free Light Chain Assay

Patients with a markedly abnormal involved/uninvolved FLC ratio (≥100) have been redefined as having MM if they meet other criteria required for the diagnosis. Elevations that are less marked are a risk factor for progression. In a study of 273 patients with SMM, an abnormal involved/uninvolved FLC ratio ≥8 were at increased risk of progression (HR, 2.3; 95% CI, 1.6 to 3.2) with a 25% per year risk of progression in the first 2 years.[24]

Multiparametric Flow Cytometry

Immunophenotyping with multiparametric flow cytometry is useful in determining prognosis in SMM by accurately distinguishing and quantitating BMPCs with malignant potential from normal PCs. Abnormal plasma cell immunophenotype can be defined as expression of CD56, lack of expression of CD19 and/or CD45, or weak expression of CD38. The risk of progression in SMM is significant if >95% plasma cells in the bone marrow have an abnormal immunophenotype.

Cytogenetic Abnormalities

A Mayo Clinic series of 351 patients with SMM found that patients with t(4;14) and/or del(17p) have a higher risk of progression.[25] Similar results have also been reported by a German study as well. Gene expression profiling (GEP) signatures may offer additional prognostic information, but clinical utility is limited.

Change in Monoclonal Protein Level

One of the most important variables associated with a high risk of progression in SMM is change in M protein levels over time. In a Mayo Clinic study of 90 patients with SMM, a rise in the M protein level over 6 months (evolving M protein) was associated with a significant increase in risk of progression.[26] The 2-year progression rate was over 80% in persons with evolving M protein levels and a decrease in hemoglobin of 0.5 g/dL or more.

RISK STRATIFICATION

Multiple risk stratification models are available for risk stratification of SMM. The Mayo Clinic 2018/IMWG 2019 risk stratification model is given in Table 90.7.[27]

The three high-risk factors in this model are if the BMPCs >20, if the serum M protein level >2 g/dL, and if the serum involved/uninvolved FLC ratio >20. Presence of two or three of these factors is associated with a median TTP to MM of approximately 2 years and is considered high-risk SMM.

TABLE 90.7 **Risk Stratification of Smoldering Multiple Myeloma**[a]

Mayo 2018 Criteria
High-Risk SMM (Median Time to Progression 2 Years)
Any 2–3 of the following high-risk factors:
Serum M protein > 2 g/dL
Serum free light chain ratio (involved/uninvolved) >20
Serum M protein ≥30 g/L
Bone marrow plasma cells >20%
Intermediate-Risk SMM (Median Time to Progression 5 Years)
Any 1 high-risk factor
Low-Risk SMM (Median Time to Progression 10 Years)
No high-risk factor
Other High-Risk Factors
Progressive increase in M protein level (evolving type of SMM)[b]
Bone marrow clonal plasma cells 50%–60%
t (4;14) or del 17p or 1q gain
Increased circulating plasma cells
MRI with diffuse abnormalities or with one focal lesion
PET-CT with focal lesion with increased uptake but without underlying osteolytic bone destruction

[a] Patients who are high risk by Mayo 2018 criteria are candidates for prophylactic therapy with lenalidomide or lenalidomide plus dexamethasone in the absence of clinical trials.

[b] Increase in serum monoclonal protein by ≥25% on two successive evaluations within a 6 month.

M, Monoclonal; *MRI*, magnetic resonance imaging; *PET-CT*, positron emission tomography-computed tomography; *SMM*, smoldering multiple myeloma.

Therapy

Multiple studies have been conducted to determine if early therapy can delay progression and improve overall survival in SMM.[2] Many early studies failed to show significant benefits. In a randomized trial, Witzig et al. compared thalidomide plus zoledronic acid versus zoledronic acid alone in patients with SMM.[28] The TTP was superior for patients treated with thalidomide plus zoledronic acid ($n = 35$) compared with zoledronic acid alone ($n = 33$); median TTP 2.4 years (95% CI: 1.4 to 3.6) versus 1.2 years (95% CI: 0.7 to 2.5), respectively, $P = .02$. However, there were no significant differences in overall survival, and there was toxicity from therapy with thalidomide, especially neuropathy.

More recently, studies have found that early therapy with lenalidomide offers significant clinical benefit for patients with high-risk SMM (see box on Approach to Smoldering Multiple Myeloma). In a randomized trial in high-risk SMM conducted by the Spanish Myeloma group, TTP was significantly longer in patients treated with lenalidomide plus dexamethasone (Rd) compared with observation, $P < .001$.[29] Overall survival was also significantly longer with Rd compared with observation. An ECOG trial comparing lenalidomide alone versus observation in high-risk SMM has confirmed the findings of the Spanish trial.[30] In this trial, early therapy with lenalidomide significantly prolonged time to end-organ damage in patients with intermediate and high-risk SMM, hazard ratio, 0.28; 95% CI, 0.12 to 0.62; $P = .002$). The 3-year PFS was 91% for the lenalidomide arm versus the 66% for the observation arm. The benefit was highest in patients with high-risk SMM by the Mayo 2018/IMWG 2019 (20-2-20) risk-stratification model, hazard ratio, 0.09, 95% CI, 0.02 to 0.44). Based on these two trials, patients with newly diagnosed high-risk SMM patients should be considered for early intervention with lenalidomide or Rd given for a time-limited duration of approximately 2 years (Fig. 90.7). An ongoing ECOG randomized trial is testing whether a standard myeloma therapeutic triplet daratumumab, lenalidomide, dexamethasone (DRd) will be superior to prophylactic doublet therapy with Rd.

The role of bisphosphonates to delay bony events in SMM is still unclear.[2] In a randomized trial a reduction in skeletal-related events (SREs) was noted with pamidronate administered monthly for 1 year, compared with observation. Similar results have also been seen in a randomized trial of zoledronic acid (4 mg once a month for 12 months) versus observation. Based on these studies, bisphosphonates every 3 to 4 months can be considered for selected high-risk SMM patients.

Other trials are exploring agents such as daratumumab and isatuximab in an attempt to delay progression of SMM to symptomatic MM. Patients with high-risk SMM are also candidates for clinical trials testing during early intervention, some of which are testing intensive therapy with curative intent.

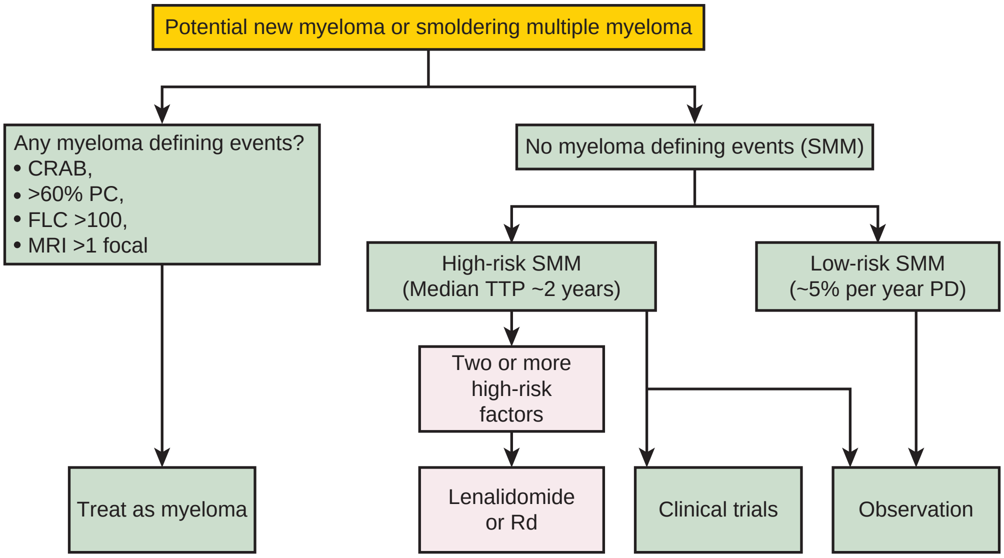

Figure 90.7 APPROACH TO THE MANAGEMENT OF SMOLDERING MULTIPLE MYELOMA. *CRAB*, Hypercalcemia, renal failure, anemia, bone lesions attributable to the plasma cell disorder; *FLC*, free light chain; *MRI*, magnetic resonance imaging; *PD*, progressive disease; *TTP*, time to progression; *Rd*, lenalidomide plus dexamethasone; *SMM*, smoldering multiple myeloma.

APPROACH TO SMOLDERING MULTIPLE MYELOMA

In patients with low- and intermediate-risk SMM, follow-up is needed every 3–4 months, on a long-term basis. In patients with high-risk SMM, therapy with lenalidomide alone, or with lenalidomide plus low dose dexamethasone is recommended. These patients are also candidates for clinical trials evaluating more aggressive treatment options, especially addition of monoclonal antibodies. There are limited data on duration of therapy. In general, we would recommend therapy for a limited duration of 2 years, and then observe. Therapy can be resumed if there is evidence of rise in M protein levels. Patients with high-risk SMM must be followed with annual bone imaging, to detect bone progression. We would also recommend pamidronate or zoledronic acid once a month for 12 months in these patients for bone prophylaxis.

FUTURE DIRECTIONS

SMM is a heterogeneous entity and often misunderstood as an intermediate stage between MGUS and MM. Our current paradigm recognizes that SMM actually comprises of two distinct groups of patients who, on the surface, meet the same diagnostic criteria, but are quite different from a biological standpoint. Thus approximately half of the patients with SMM have asymptomatic malignancy (high-risk SMM) that is destined to progress in a matter of time, and the other half have true biologic premalignancy (MGUS), which has a random, but low risk of progression. This knowledge has helped advance risk stratification and therapy. Thus using the current risk-stratification models, we are able to identify patients who have asymptomatic malignancy (high-risk SMM) and offer them intervention. In the future, we need to identify additional biomarkers to accurately identify this group. High-risk patients with SMM have a very similar genetic landscape as MM, and any new risk factor we identify will need to show incremental value to currently available clinical biomarkers. In addition, we must also study the role of the microenvironment and the immune system in the progression of SMM to determine if such factors can increase the predictive value of existing biomarkers, which are mainly focused on the plasma cell.

The other area of ongoing investigation is focused on improving outcome of high-risk SMM beyond therapy with lenalidomide or with Rd. Trials are going on with daratumumab as a single-agent, as well as comparing Rd (preventive therapy) to daratumumab plus Rd (myeloma-like therapy). More important is the question whether early therapy with aggressive regimens can cure a subset of patients with SMM. These issues need well-designed clinical trials. The long natural history of SMM makes interpretation of these trials in a timely manner difficult, hence why we also need to validate surrogate endpoints such as sustained minimal residual disease (MRD) negative state.

Finally we also need studies to determine whether screening for SMM can be beneficial, particularly in high-risk groups such as Blacks, as well as first-degree relatives of patients with MM.

CHAPTER 91

MULTIPLE MYELOMA

Sydney X. Lu, Even H. Rustad, Saad Z. Usmani, and C. Ola Landgren

Clonal plasma cell (PC) neoplasms are comprised of a number of interrelated and partially overlapping entities, ranging from benign to fully malignant, which are variously defined and categorized by burden of disease, presence of organ injury, anatomic location, and in some cases, unique constellations of signs, symptoms, and pathologic findings (see box on Rare Disorders Associated With Monoclonal Proteins and/or Plasma Cells, and also Chapters 90 and 93). As the majority of neoplastic PCs are functional with respect to secreting clonal immunoglobulins and/or their fragments (i.e., free light or heavy chains), as well as cytokines, growth factors, and other signaling molecules, these abnormal proteins can become relevant both in the pathophysiology of PC disorders, manifesting (e.g., as kidney injury, neuropathy, cardiac impairment, hyperviscosity, etc.) and can also frequently serve as useful biomarkers for evaluating disease burden and response to treatment. This chapter highlights continued advances in both knowledge regarding the underlying pathophysiology of PC neoplasms, and their therapy, with a focus on multiple myeloma (MM) as the prototypical malignant PC disorder. In this context we emphasize minimal residual disease (MRD) testing for risk stratification, disease management, and decision making, and also highlight novel therapies with mechanisms-of-action beyond existing proteasome inhibitors (PIs), immunomodulatory agents, and monoclonal antibodies.

SCREENING, EPIDEMIOLOGY, AND RISK FACTORS

MM, the dominant malignant PC disorder, accounts for 1.8% of all malignancies and is the second most common hematologic malignancy. It is estimated that in 2016, there were about 138,500 incident cases and 98,500 deaths attributed to MM globally.[1,2]

Age is a major risk factor for MM as well as its precursor states, smoldering myeloma (SMM) and monoclonal gammopathy of undetermined significance (MGUS) (see Chapter 90). Generally, MM is a disease affecting a relatively older population with a median age at diagnosis of 69 years (Fig. 91.1A), and less than 2% to 5% of patients are younger than 40 years old at diagnosis. Myeloma is more frequent in men than in women, and in African Americans than in White persons in the United States (see Fig. 91.1B). The incidence of MM in African American men is approximately 15.7 per 100,000 per year as compared with 11.5 per 100,000 per year in African American women; the corresponding incidence rates are 7.7 and 4.5 per 100,000 in White men and women, respectively. In addition, African Americans also generally present with MM earlier in life than Whites. Although there has been an increase in the incidence of MM over time, this can be attributed to better detection and surveillance of the disease, overall aging of the population worldwide, together with increased prevalence attributable to markedly longer median overall survival (OS) of patients in the era of modern therapies, with the current median OS for undifferentiated newly diagnosed MM patients likely longer than 6 years.[3]

In addition to the precursor neoplasms MGUS and SMM (see Chapter 90),[4] which are believed to be obligatory precursors to MM, increasing age and certain racial groups are known predisposing conditions. Other risk factors for MM include human immunodeficiency virus (HIV) infection[5] (ameliorated in the era of effective antiviral therapy), obesity, and certain occupations,[6] as well as exposure to specific chemical carcinogens, including Agent Orange (linked to MGUS[7]). Although clusters of familial MM have been described in the literature, they are rare and are not believed to contribute significantly to the overall epidemiology of MM. Recent genetic studies have identified mutations of LSD1 (KDM1A),[8] DIS3,[9] and Lynch syndrome (deoxyribonucleic acid [DNA] mismatch repair) genes as being associated with familial myeloma. In addition, Gaucher syndrome,[10] a lysosomal storage disorder, is also associated with an elevated risk of developing MM. As malignant PC disorders are rare overall, there are currently no guidelines from national organizations or scientific societies endorsing screening for PC disorders in the asymptomatic general population.

PATHOGENESIS

The transformative event which initiates the trajectory toward MM occurs in a germinal center B cell that has undergone somatic hypermutation and class-switch recombination (with the exception of rare cases of immunoglobulin M [IgM]-myeloma).[11] Epidemiological and genomic studies have indicated that initial transformation often occurs in the first three decades of life.[12–15] Years after immortalization of the first plasma cell, when the clonal population has expanded sufficiently, they produce detectable serum monoclonal proteins. Based on clinical features, the condition may be classified as MGUS or SMM.[16,17] In a minority of patients, clonal plasma cells acquire additional driver, leading to the development of MM and eventually relapsed/refractory disease with a highly aggressive phenotype.[11,16]

Genomic Landscape of Multiple Myeloma at Presentation

Large-scale studies mapping the driver mutational landscape of MM at presentation have focused on three types of somatic alterations: recurrent translocations involving the immunoglobulin gene loci, copy number alterations (CNAs), and single nucleotide variants (SNVs) (Fig. 91.2A) (see Chapter 57). Moreover, these early studies focused on alterations detectable by conventional cytogenetics, fluorescence in situ hybridization (FISH), array-based copy number analysis, and whole exome sequencing. More recently, whole-genome sequencing (WGS) studies have added another level of complexity and highlighted areas that remain poorly understood. In one recent WGS study, the median number of SNVs in a tumor was 5377 (range 982 to 15738), with a median of 26 (range 0 to 129) structural variants (SVs), including translocations, inversions, deletions, and tandem duplications, which often combine to form complex SVs. Patients who were highly similar in their recurrent driver profile often displayed striking differences in mutational burden and SV landscape (see Fig. 91.2B). Extracting the biologically important information from this complex panorama of somatic alterations is a major goal of ongoing research.

In the following sections we summarize the main pillars and recent advances in MM genomics, focusing on overall principles and potential genomic biomarkers. We have taken a chronological perspective, starting with the earliest events which led to initiation of monoclonal gammopathy, followed by the key mutational processes and genomic alterations which appear to drive the evolution to overt MM and beyond.

RARE DISORDERS ASSOCIATED WITH MONOCLONAL PROTEINS AND/OR PLASMA CELLS

- POEMS[221, 222]: polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes. Typically presents with osteosclerotic rather than frankly lytic bone lesions, and may also co-occur with Castleman disease. POEMS is associated with elevated vascular endothelial growth factor (VEGF) levels, which are helpful in diagnosis and assessing therapy response. Assessing for endocrinopathy at diagnostic evaluation and co-management with an expert endocrinologist may be helpful. POEMS carries a better prognosis than conventional multiple myeloma.
- TEMPI[223, 224]: telangiectasias, erythrocytosis, monoclonal protein, perinephric fluid collections, intrapulmonary shunt. A rare disorder which can be efficaciously treated with bortezomib and daratumumab. Autologous transplant is rarely required.
- AESOP[225–227]: adenopathy and extensive skin patch overlying a plasmacytoma. This is considered a paraneoplastic syndrome which can co-occur with POEMS, Castleman disease, plasma cell disorders as well as lymphoplasmacytic lymphoma.
- Schnitzler syndrome[228, 229]: an autoinflammatory and rheumatologic disorder associated with M-protein, which may also be associated with splenomegaly, lymphadenopathy, and chronic urticaria. Managed primarily with the IL-1 receptor antagonist anakinra rather than anti-neoplastic therapy per se.
- Cryoglobulinemia type I[230]: monoclonal IgG, IgM, IgA, or free light chains which can be associated with hyperviscosity syndrome and vasculitis.
- Heavy chain diseases: a rare assortment of B lymphoproliferative disorders, typically associated with indolent lymphomas, which produce heavy chains (generally α, γ, μ) which are deposited in tissues, without intact light chains. Variable clinical course. Managed with observation, supportive care (e.g., antibiotics for infections), and anti-lymphoma or anti-myeloma therapy.
- Primary amyloidosis—see Chapter 93 on AL amyloidosis.
- Chronic neutrophilic leukemia associated with plasma cell dyscrasias (see Chapter 72).[231, 232]
- Monoclonal gammopathy of renal significance13: these disorders are characterized by low-level clonal plasmacytosis and paraproteinemia causing renal injury. Although they may not meet criteria for MM, therapy may be considered.

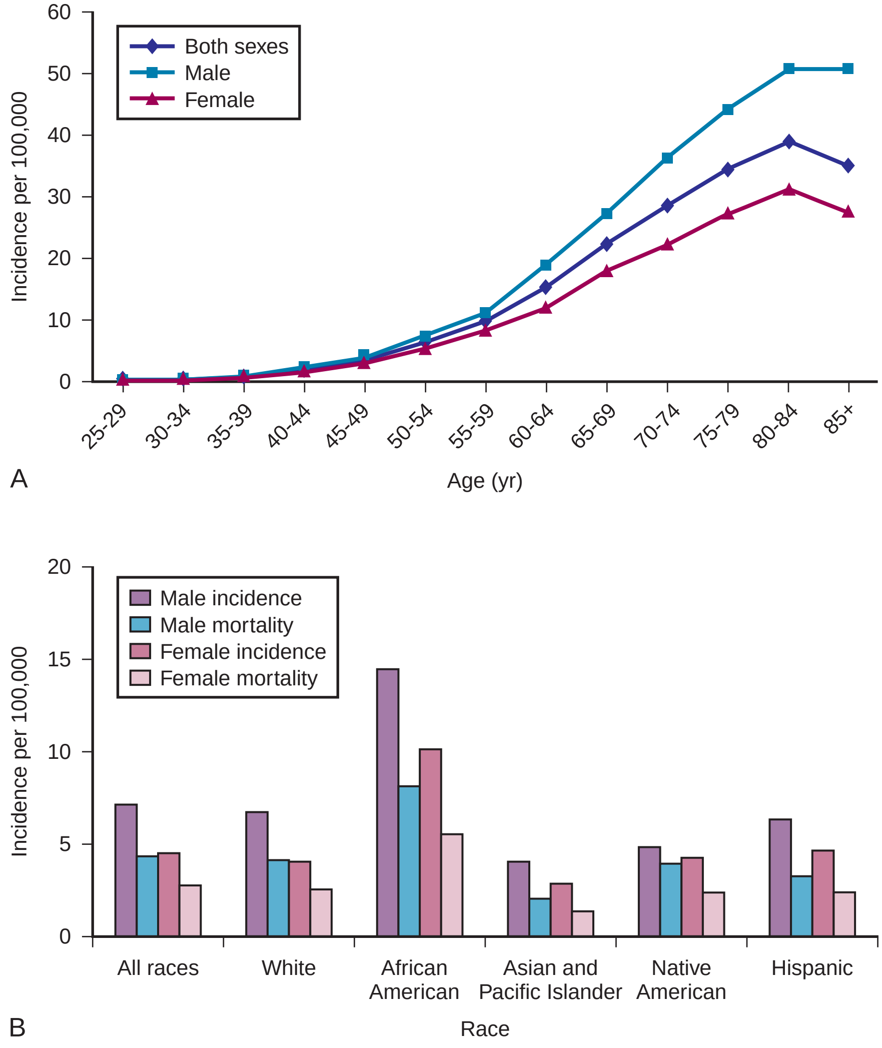

Figure 91.1 MULTIPLE MYELOMA EPIDEMIOLOGY. (A) Multiple myeloma (MM) average annual age- and gender-specific incidence per 100,000 in the United States in 2009. (B) MM average annual race-specific incidence per 100,000 in the United States in 2009. Increase in incidence is noted with advancing age; the incidence is greater in males than in females; and a higher incidence is observed in African American than in White populations.

Primary Genomic Driver Events

Traditionally, MM has been divided into molecular subgroups based on the presumed initiating driver event. Forty percent of patients have a translocation involving the immunoglobulin heavy chain (*IGH*) locus on chromosome 14 and one of seven canonical partner oncogenes: *CCND1* (t11;14), *CCND2* (t12;14), *CCND3* (t6;14), *MMSET* (t4;14), *MAF* (t14;16), *MAFA* (t8;14), and *MAFB* (t14;20).[18]

These events drive disease development by placing key oncogenes under the transcriptional control of the *IGH* enhancers, a phenomenon known as super-enhancer hijacking. Sequencing analysis of the *IGH* locus in primary translocations most commonly reveals a breakpoint in the class-switch recombination regions, consistent with DNA double-strand breaks introduced by activation-induced cytidine deaminase (AID) in the germinal center. Sixty percent of patients have a hyperdiploid genome (HRD), defined by three or more trisomies of odd-numbered chromosomes. Chromosomes 9, 15, 19, and 21 are usually acquired first, which may be followed by gain of additional copies of the same or different chromosomes, typically 3, 5, and 7.[19,20] Although not considered part of hyperdiploidy, gain of chromosome 1q may occur in the same early time-window and play a role in disease initiation. The etiology of whole chromosome gains in MM remains unknown. Approximately 5% of patients have both HRD and a canonical *IGH* translocation and <10% of patients have neither. Some patients may be driven by other rare genomic rearrangements, including translocations involving *IGH* and rare partners such as the B-cell master regulator *PAX5* or the co-stimulatory molecule *CD40*.[18] Gene expression profiling (GEP) studies have confirmed the importance of primary *IGH*-translocations and HRD as drivers of MM biology, while providing additional refinement.[21–23] Clinically, *IGH* translocations involving *MMSET*, *MAF*, and *MAFB* have been associated with poor prognosis. However, the penetrance of this "high-risk" genotype at the individual patient level is variable, with many of these patients achieving long-term disease control using modern highly effective therapies. Furthermore, the prognostic impact of primary driver events is most likely modulated by the combination of secondary drivers present in each individual patient, although these higher-order interactions are thus far poorly understood.

Genomic Drivers of Progression From Precursor to Myeloma and Beyond

There is currently no single genomic abnormality that separates MM from its precursors, or from advanced relapsed/refractory disease. Instead, there is a gradual increase in genomic complexity over time, characterized by the accumulation of somatic alterations of all types. This evolutionary process follows preferred trajectories, where the early drivers determine which additional hits will confer the greatest advantage and therefore end up being selected (some such common interactions are highlighted by the clusters in Fig. 91.2A). There are also more general temporal patterns, where oncogene activation tends to occur earlier (e.g., copy number gains, super-enhancer hijacking and gain of function SNVs), while tumor suppressor gene inactivation occurs later (e.g., copy number loss and truncating SNVs).

Key gain-of-function drivers in MM include activation of *MYC* through a variety of mechanisms including translocation with an immunoglobulin locus (i.e., *IGH*, *IGL*, or *IGK*), which is particularly enriched in the HRD subgroup, as well as gain of one or more copies of chromosome 1q. *MYC* is a transcriptional master regulator in MM along with *IRF4*, and knock–down of both factors in vitro lead to cell death. Gain of 1q usually involves the whole chromosome arm, but a minimally amplified region on 1q21.3 has led to identification of the putative driver gene *CKS1B*. Nuclear factor-kappa B (NFκB) pathway activation is a recurrent feature where different types of genomic alterations converge, including recurrent deletions of the NFκB inhibitor (16p.12), while the MAPK pathway genes, *NRAS*, *KRAS*, and *BRAF*, are predominantly affected by SNVs. Given that MAPK mutations in MM are acquired relatively late and most commonly are subclonal, the rationale for targeted therapy using MEK and/or BRAF inhibitor is

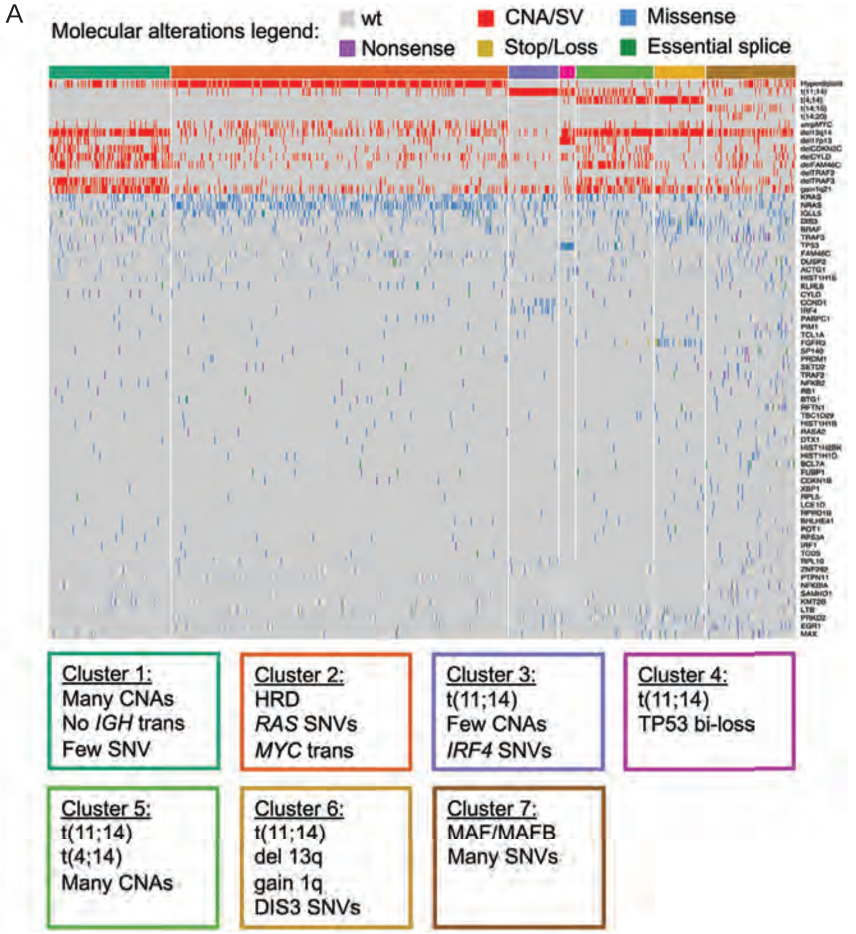

Figure 91.2 GENOMIC CLASSIFICATION OF MULTIPLE MYELOMA. (***Continued***)

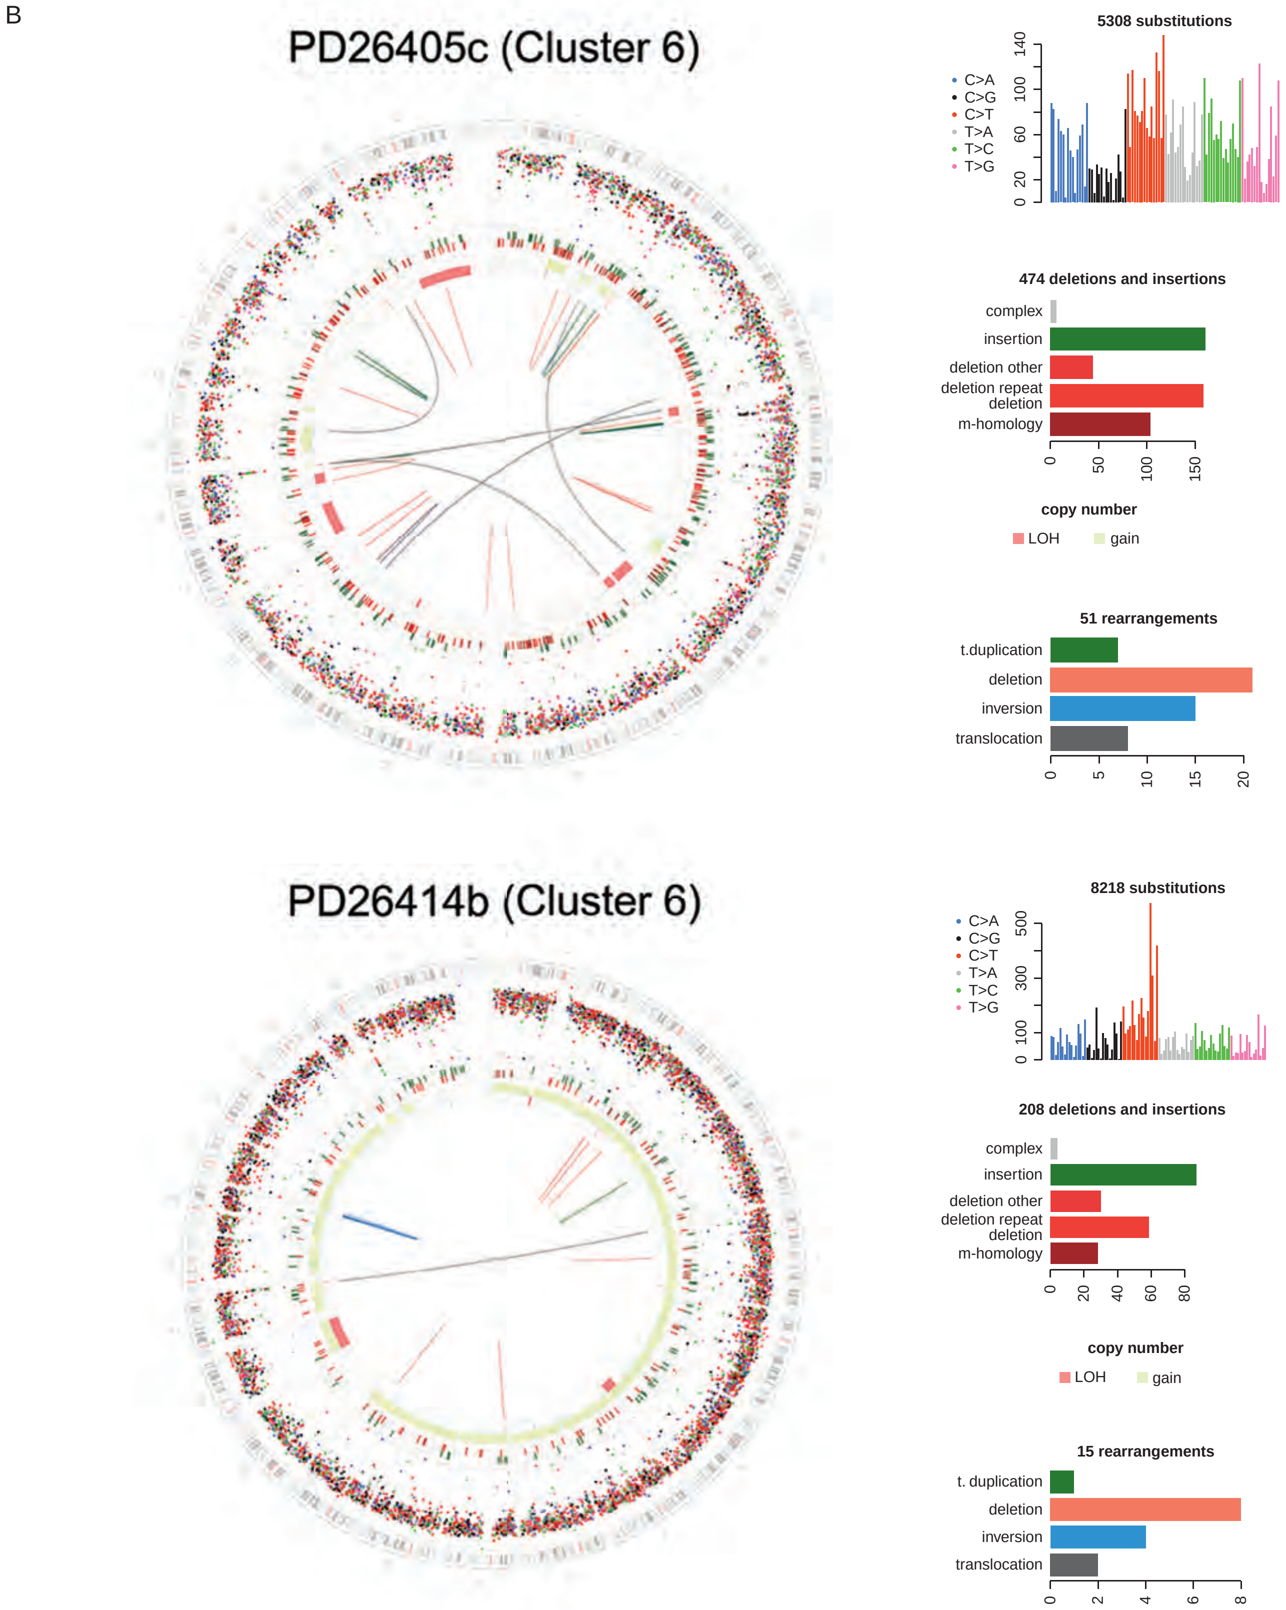

Figure 91.2–cont'd Genomic classification of multiple myeloma. (A) Heatmap of 724 patients with newly diagnosed multiple myeloma assigned to one of seven genomic subclasses of multiple myeloma defined by recurrent translocations, copy number alterations *(CNAs)*, and single nucleotide variants *(SNVs)*. Each column represents a patient and each row a molecular alteration (color legend above heatmap). Defining features of each cluster (color coded on the top row) are displayed in boxes below the heatmap. (B) Circos plots showing the genome-wide landscape of genomic alterations in two patients belonging to cluster 6 (*orange*) in panel (A), with legend and summary data to the right. Chromosomes are plotted around the outer plot margin, followed by concentric circles representing SNVs, CNAs, and structural variants *(SVs)*. Although both cases harbor defining features of cluster 6 (e.g., t[11;14] and del 13q), they differ strikingly in SNV burden and genome-wide profile of CNAs and SVs. *(The molecular classification and heatmap has been adapted from Maura F, Bolli N, Angelopoulos N, et al. Genomic landscape and chronological reconstruction of driver events in multiple myeloma. Nat Commun. 2019;10[1]:3835.)*

weaker than in diseases where MAPK inactivation is an early or initiating feature, such as hairy cell leukemia and *BRAF*-mutant melanoma.

Loss-of-function events in MM tend to converge on established tumor suppressor genes involved in cell cycle regulation, such as *TP53* (17p13), *RB1* (13q14), and *CDKN2C* (1p.32). Tumor suppressor genes more specific to MM include *FAM46C* (1p12), a regulator of messenger RNA (mRNA) polyadenylation, and *DIS3* (13q21), encoding the catalytic subunit of the human exosome complex.[24,25]

Multiple studies have investigated the prognostic impact of secondary genomic drivers, often with conflicting results. Two alterations have been thoroughly established as independent prognostic factors across several studies: bi-allelic inactivation of *TP53* and amplification of 1q21. Deletion of 17p has long been considered a marker of poor prognosis, but recent studies including SNV data has shown that this phenotype depends on inactivating mutation of *TP53* on the remaining allele. For gains of 1q21, there appears to be a dose response relationship between the number of copies and prognosis, where having four or more copies is associated with particularly poor outcomes.

Recent efforts have begun to reveal the mutational process shaping the evolving genome of MM. We will highlight here three findings of particular clinical importance. First, a hyper-mutator phenotype in MM has been identified in <5% of patients, driven almost entirely by the APOBEC family of cytidine deaminases. High burden of APOBEC-induced mutations is associated with poor prognosis independently from other genomic features, despite many of these patients also having *IGH*-translocations involving *MAF* or *MAFB*. The mechanisms underlying aberrant APOBEC activation in MM and how this might be exploited therapeutically is subject to ongoing investigations. Second, complex SVs termed chromothripsis have been identified as key driver events in up to 24% of patients with MM and are strongly associated with poor prognosis. Chromothripsis is the result of shattering and re-joining of one or more chromosomes, resulting in widespread genomic rearrangements. This is particularly important because it means that a high level of genomic complexity including multiple driver events can be acquired by a single cell at a single point in time, which may contribute to the dramatic changes in clinical behavior that can sometimes be observed in MM. Finally, recent studies have identified mutational signatures specifically associated with prior exposure to melphalan and platinum-containing chemotherapies used as an anti-myeloma therapy. This is perhaps not surprising, since the mechanism of action of these agents is cell-cycle arrest through the introduction of DNA damage. Nonetheless, having identified the specific mutational footprint of these therapies, one can begin to explore their role in development of treatment resistance as well as secondary malignancies. In particular, myelodysplastic syndromes and acute myeloid leukemia (AML) are strongly enriched in MM patients following melphalan therapy. With life expectancies exceeding 10 years for many patients with MM receiving state-of-the-art therapies, long-term toxicity is becoming an increasing concern which may warrant more restrictive use of cytotoxic agents.

In summary, the panorama of genomic drivers in MM is characterized by a limited number of frequent alterations followed by a long tail of rare drivers. Evolution from precursor stages to MM and acquisition of an increasingly aggressive and treatment-refractory phenotype usually results from accumulation of multiple genomic hits over time, converging on pathways responsible for cell proliferation and survival. In some cases, accelerated or "punctuated" evolution may occur as a result of complex SVs introducing multiple drivers in a single genomic event. We anticipate that improved understanding of the processes shaping tumor evolution and how multiple genomic drivers interact to determine tumor biology will lead to the emergence of clinically meaningful MM molecular subgroups.

CLINICAL IMPLICATIONS OF CLONAL HETEROGENEITY AND EVOLUTION

In any given patient with MM, a number of distinct subclones of disease are present which differentially populate the bone marrow and soft tissue lesions inside and outside of the skeleton. Tumor phylogenies reconstructed from multiple biopsies at presentation indicate early seeding from a common disease site followed by local expansion.[26,27] Presence of high-risk features in a single lesion conferred the same adverse prognosis as if every site shared the same high-risk profile. At the extreme end, in multi-regional biopsies obtained at autopsy, there is evidence of accelerated seeding where tumor sites throughout the body have been re-populated by descendants of a single cell which survived intensive therapy.[27] Although the number of patients analyzed with high spatiotemporal resolution remains low, the current evidence indicates that high-risk subclones determine the final outcome of disease but may take years and multiple lines of therapy before emerging as dominant. This time lag may reflect the need of tumor subclones to acquire multiple cooperating driver lesions to achieve their full malignant potential and the gradual increase of immunosuppression resulting from both chronic disease and multiple lines of therapy.

IMMUNE AND BONE MARROW MICROENVIRONMENT

In addition to cell-intrinsic genomic changes and other aberrancies within neoplastic PCs, MM also exhibits a strong dependence on the microenvironment as a feature of disease pathogenesis.[2] Neoplastic PCs both rely on, and in turn promote, an abnormal bone marrow and immune microenvironment as a key feature of oncogenesis (Fig. 91.3).[28] The complex interplay between malignant PCs and their heterogeneous microenvironment, which includes endothelium, osteoblasts, osteoclasts, and a variety of other mesenchymal and stromal cell types, as well as myeloid and lymphoid hematopoietic and immune cell subsets,[29] soluble molecules including growth factors, cytokines, and secreted receptor molecules, as well as diverse extracellular matrix components including collagen and other structural proteins, explains in part some of the clinical features of PC disorders, and has also been increasingly targeted, directly or indirectly, in therapy of these disorders.

The effect of PCs within their environment can reflect disease evolution. For example, in precursor states prior to the development of frank MM, the PETHEMA and Scandinavian[30] groups have shown that biomarkers such as the ratio of abnormal to total plasma cells in the marrow, which reflects in part the paracrine suppression of normal B cell to plasma cell maturation and function, as well as the reciprocal suppression of uninvolved immunoglobulins (termed "immunoparesis" [e.g., low IgA and IgM] in a case of IgG plasma cell neoplasm) can risk-stratify patients for risk of progression to MM, with immunoparesis and high ratios of abnormal to total plasma cells associated with increased risk.[31] With respect to MM and anemia as a defining criterion, this is in large part also believed to be mediated via paracrine effects of malignant PCs suppressing erythropoiesis.[32] Finally, imbalanced osteoblastic vs. osteoclastic activity with resultant bone lesions and hypercalcemia are arguably the *sine qua non* features of MM. Finally, although not considered a myeloma-defining criterion, impaired cellular and humoral immunity in patients with PC disorders, with resultant infectious complications, arguably also reflects the deleterious effects of neoplastic PCs on the immune microenvironment. Given this, dysregulated B and plasma cell maturation and function, disordered erythropoiesis, and imbalanced osteoblastic versus osteoclastic activity represent some commonly observed clinical examples of neoplastic PCs acting to create an abnormal marrow microenvironment. In turn, MM is a disease most stereotypically confined to the bone marrow ("medullary disease"), with extramedullary manifestations or circulating disease in the blood, sometimes representing progression[33] as a late phenomenon, reflecting the strong dependence of both normal and neoplastic PCs on the marrow microenvironment and its many complex cell-cell interactions and paracrine signaling molecules, for their survival.

With respect to therapy, many current and investigational therapies for MM target the microenvironment, directly or indirectly. Although the many United States Food & Drug Administration (FDA)-approved agents discussed below have direct, cell-autonomous

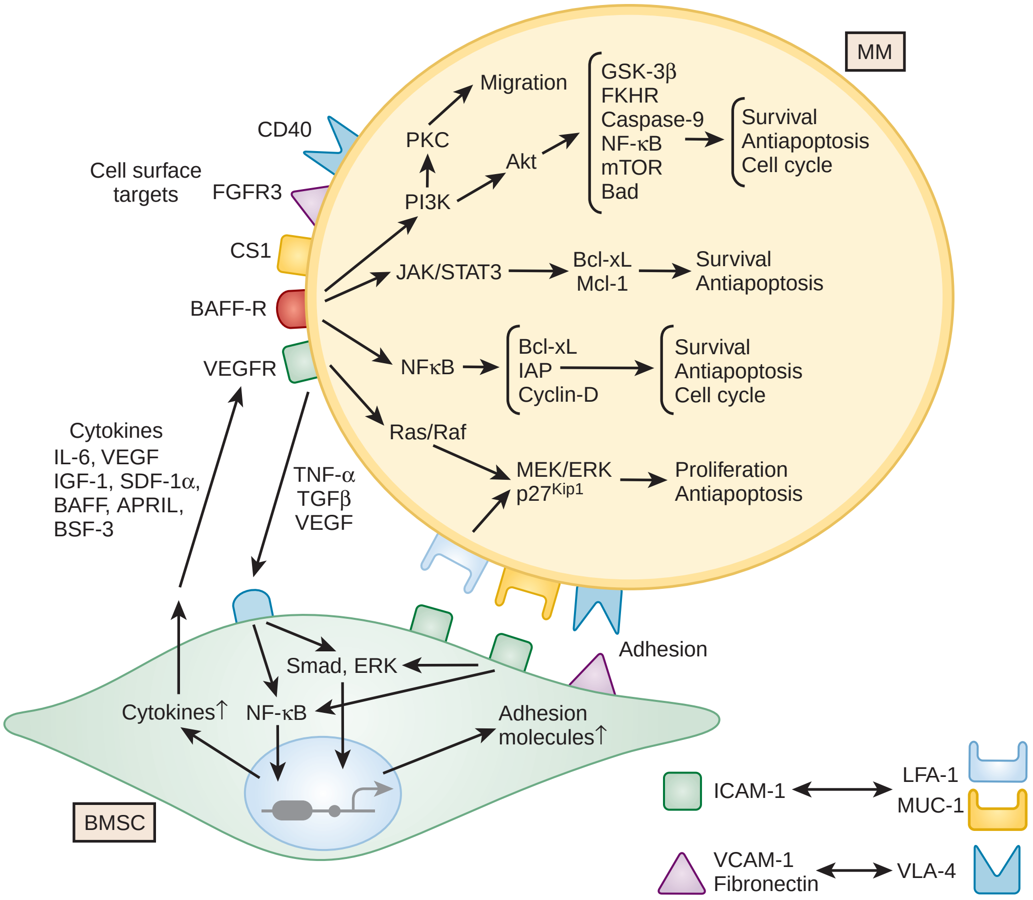

Figure 91.3 INTERACTION AND ADHESION OF MULTIPLE MYELOMA CELLS TO BONE MARROW STROMAL CELLS (BMSCS). Binding of multiple myeloma *(MM)* cells to BMSCs induces the activation of p42/p44 mitogen-activated protein kinase *(MAPK)* and nuclear factor-κB *(NFκB)* in BMSCs. The activation of NFκB upregulates adhesion molecules on BMSCs. Cytokines secreted through this interaction, including interleukin 6 *(IL-6)*, tumor necrosis factor-α *(TNF-α)*, and vascular endothelial growth factor *(VEGF)*, activate the main signaling pathways (p42/p44 MAPK, Janus kinase *[JAK]*/signal transducer and activator of transcription 3 *[STAT3]* and/or phosphatidylinositol 3-kinase *[PI3K]/AKT*) and their downstream targets, which triggers MM cell growth, survival, and migration. The RAS/RAF/mitogen-activated protein kinase kinase *(MEK)*/MAPK pathway mediates proliferation of MM cells. JAK/STAT3, along with upregulation of B-cell lymphoma extra large *(BCL-XL)* and myeloid cell leukemia-1 *(MCL1)*, mediates survival. PI3K/AKT, through downstream activation of BAD and NFκB and/or inactivation of caspase-9, mediates antiapoptosis. NFκB and forkhead in rhabdomyosarcoma *(FKHR)* modulate cyclin D and KIP1, thereby regulating cell-cycle progression. Signaling through PI3K induces downstream protein kinase C *(PKC)* activity and MM cell migration. *APRIL*, A proliferation-inducing ligand; *BAFF-R*, B cell–activating factor receptor; *BSF-3*, B-cell stimulating factor 3; *ERK*, Extracellular signal-related kinase; *FGFR3*, fibroblast growth factor receptor 3; *GSK-3β*, glycogen synthase kinase 3β; *IAP*, inhibitor of apoptosis protein; *ICAM-1*, intercellular adhesion molecule 1; *IGF-1*, insulin-like growth factor 1; *IL*, interleukin; *LFA-1*, lymphocyte function-associated antigen 1; *MM*, multiple myeloma; *mTOR*, mammalian target of rapamycin; *MUC-1*, mucin 1; *SDF-1α*, stromal cell–derived factor 1α; *TNF-α*, tumor-necrosis factor-α; *VCAM-1*, vascular cell adhesion molecule 1; *VEGF*, vascular endothelial growth factor; *VLA-4*, very late antigen 4. *(Adapted from Hideshima T, Mitsiades C, Tonon G, et al. Understanding multiple myeloma pathogenesis in the bone marrow to identify new therapeutic targets. Nat Rev Cancer. 2007;7[8]:585–598.)*

effects on neoplastic PCs, these drugs can also render the microenvironment less hospitable to PC growth. The relative importance of microenvironmental vs. direct anti-neoplastic effects of many commonly used agents are difficult to investigate in preclinical models due to the difficulty of modeling the microenvironment, and this remains an area of interest for investigators.

For example, the immunomodulatory drugs[34] (e.g., thalidomide, lenalidomide) have a particularly complex mechanism of action: in addition to acting directly on PCs to induce apoptosis by mediating the degradation of the essential transcription factors *IZKF1* and *IZKF3*[35] by coopting the endogenous ubiquitin ligase machinery to degrade these proteins as neo-substrates, lenalidomide also decreases the generation and activity of osteoclasts necessary for myeloma survival,[36–38] decreases the expression of cell adhesion molecules expressed by other marrow stromal cells which ordinarily promote PC survival, and stimulates T- and natural killer (NK)-cell anti-tumor activity by increasing immune synapse formation, increasing direct NK-mediated killing and CD8$^+$ T-cell effector function. Likewise, thalidomide is known to have anti-angiogenesis[39] and anti-VEGF[40] signaling properties which also likely account in part for its therapeutic efficacy. The other major class of novel agents is the PIs with bortezomib as the prototype agent. Again, the mechanism of action of this drug class is complex: in addition to direct anti-PC activity by inhibition of the proteasome and thus indirect downregulation of NFκB signaling,[41] among a plethora of other cell-autonomous mechanisms, bortezomib also modulates the bone marrow microenvironment,[42] inducing endothelial cell and osteoclast apoptosis,[43] and inhibiting the secretion of PC growth-promoting molecules by the microenvironment, such as IL-6, vascular endothelial growth factor (VEGF), and IGF-1. Similar effects on the balance between osteoblasts vs. osteoclasts has been observed with the irreversible proteasome inhibitor carfilzomib.[44] The newest class of FDA approved agents, the monoclonal antibodies elotuzumab (targeting signaling lymphocytic activation molecule F7

[SLAMF7], aka CS1 or CD319) and daratumumab and isatuximab (targeting CD38) also have both direct anti-neoplastic effects as well as indirect effects by modulating the immune microenvironment. For example, while elotuzumab binding to PCs mediates cell killing, its ligation of SLAMF7 on NK cells may activate NK cells,[45–47] leading to improved NK-directed killing of PCs. Daratumumab[48] not only inhibits the ectoenzymatic activity of CD38 and induces antibody-dependent cellular cytotoxicity (ADCC) of tumor cells, but has also been suggested to deplete CD38$^+$ regulatory B and T cells and myeloid-derived suppressor cells, thereby favorably altering the tumor immune microenvironment and biasing it toward effective anti-tumor immunity.[49,50] Finally, daratumumab is also believed to result in immune activation by targeting CD38$^+$ NK cells.[51] The more recently approved anti-CD38 antibody isatuximab is also believed to have similar immune-activating effects.[52] Finally, modulation of osteoclast activity, via bisphosphonates or inhibiting the RANK/RANKL axis with denosumab,[53] also inhibit osteoclast activity and osteoclastogenesis, and additionally also have been suggested to mediate an anti-angiogenic and thereby anti-PC effect.

With respect to other investigational agents, interactions between stromal cells which express the co-stimulatory ligands B-cell activating factor (BAFF) and a proliferation inducing ligand (APRIL) and malignant PCs which express the cognate receptor B-cell maturation antigen (BCMA)[54] are believed to be important for the survival of normal and neoplastic PCs, thus representing selection pressure for expression of BCMA. This requirement has been exploited with chimeric antigen receptor T cell (CAR-T cells[55]) as well as monoclonal antibody-drug conjugate-based therapies targeting BCMA (e.g., belantamab mafodotin[56]), many of which have shown promising efficacy in multiply relapsed MM patients. Other investigational efforts targeting paracrine IL-6 signaling, aberrant VEGF signaling, and secreted or cell surface molecules which mediate interactions between neoplastic PCs and the marrow microenvironment are ongoing and represent additional promising therapeutic venues.

TABLE 91.1 Clinical Features of Multiple Myeloma

Bone Destruction
Pain, fractures
Cord compression with bowel and bladder dysfunction
Radicular pain and cranial nerve abnormalities secondary to nerve compression
Hypercalcemia
Polyuria, polydipsia, nausea, vomiting, constipation
Lethargy and altered mental status
Renal Failure
Nausea, vomiting, weakness, malaise
Refractory electrolyte abnormalities, volume status abnormalities
Amyloidosis
Peripheral neuropathy, autonomic neuropathy (e.g., orthostasis)
Dependent edema
Organomegaly and organ dysfunction (e.g., heart failure, jaundice)
Marrow Infiltration
Anemia, thrombocytopenia (late event)
Bleeding tendency
Reduced Immunoglobulins
Recurrent infections
Pneumonia
Cryoglobulins
Raynaud phenomenon
Acrocyanosis
Hyperviscosity
Shortness of breath
Transient ischemic attacks
Deep vein thrombosis
Retinal hemorrhage
Epistaxis

CLINICAL MANIFESTATIONS

Patients with MM may present with signs and symptoms that are most commonly related to either marrow infiltration by plasma cells and paracrine disruption of physiologic hematopoiesis, or end-organ damage manifested by renal dysfunction, bone lesions, hypercalcemia, and/or immune dysfunction.[2] However, in a minority of patients, MM may present asymptomatically or even without frank end-organ damage at all, with this group of patients diagnosed on the basis of laboratory or radiologic abnormalities, with investigations generally prompted by initial abnormalities in routine studies performed for other indications. In some patients, signs and symptoms may also be related either to deposition of paraproteins in various organs, such as the heart, kidneys, or neural tissue, as either light chain, amyloid, or very rarely, heavy chain deposits or secondary to the humoral effects of cytokines or other secreted molecules such as IL-6 or VEGF produced by the myeloma cells and/or the bone marrow microenvironment (see box on Rare Disorders Associated With Monoclonal Proteins and/or Plasma Cells). Various clinical features of myeloma are summarized in Table 91.1.

Bone Disease

Almost two-thirds of patients with MM present with bone pain and/or destructive, generally lytic bone lesions as a major symptom. Arguably, bony injury and the resulting pain and functional limitations from skeletal injury are the cardinal symptoms of myeloma which affects quality of life. As discussed above, bone disease is believed to primarily represent unbalanced hyperactivity of osteoclasts and suppression of osteoblastic activity, although direct infiltration of bone by myeloma cells also causes bone destruction. Bone modifying agents including bisphosphonates and RANKL inhibitors can reduce the number of skeletal-related events (SREs) in MM (see Skeletal Protection, below), although risks of renal injury and complications such as atypical fractures and jaw osteonecrosis must be considered. Previous studies have shown a modest OS benefit for the use of these bone-modifying agents, but they were largely performed in the era when markedly less potent induction regimens were used—the survival benefit for these agents in the modern era of potent induction therapies and relapsed/refractory disease therapies is uncertain at present, with the use of bone resorptive agents primarily viewed as adjunctive therapy by most practitioners.

Skeletal injury of the axial and appendicular skeleton can additionally result in hypercalcemia (discussed below) and may contribute secondarily to renal injury, and the functional limitations and immobility associated with skeletal injury can predispose to additional complications, such as loss of muscle mass (sarcopenia) and decreased overall physiologic reserve, increased infection risk, neurologic injury, or thrombotic events. Management is primarily focused on anti-PC therapy and anti-resorptive therapy, although pain control, physical therapy, and local therapies (e.g., kyphoplasty for vertebral fractures, surgery or radiation for cord compression or impending fractures) must be prioritized as clinically appropriate. Finally, note that healing or recovery of existing bone lesions is variable even with effective anti-PC therapy, and the lack of radiologic resolution of a lytic lesion does not necessarily indicate treatment resistance.

Hypercalcemia

Hypercalcemia is observed in approximately 25% to 30% of patients with MM and is usually a manifestation of higher disease burden. In contrast to solid tumors where hypercalcemia is generally a terminal event late in the disease course, hypercalcemia in MM more commonly occurs early, oftentimes prior to initiating effective therapy, and is eminently reversible in essentially all cases. In a minority of cases, hypercalcemia can be a manifestation of relapsing disease. Its occurrence is related to direct bone involvement by PCs with local bony injury as well as production of various cytokines that lead to increased bone resorption and calcium release at distant sites. Hypercalcemia manifests as mental status changes, lethargy, nausea and vomiting, and constipation, and can also induce renal failure directly by injuring the parenchyma, as well as by causing volume depletion. Symptomatic hypercalcemia should be managed as a hematologic emergency: adequate hydration, the use of calcitonin and steroids can temporize hypercalcemia for several days while definitive therapy, generally in the form of anti-PC therapy and/or bone modifying agents are initiated. The use of bisphosphonates or a RANKL inhibitor (denosumab) (often more appropriate when patients present with concomitant renal failure) requires the careful serial monitoring of serum total and ionized calcium as well as phosphorus levels and appropriate correction, as *hypo*calcemia after treatment with these agents has been reported.[57,58] Risks and rewards of using anti-resorptive agents in patients who have not yet had dental clearance must be weighed and cautiously considered.

Renal Failure

Renal insufficiency in the context of PC malignancies is a frequent and serious complication with a frequently multifactorial etiology, with significant implications for therapy. Monoclonal gammopathy of renal significance (MGRS)[59] (see box on Rare Disorders Associated With Monoclonal Proteins and/or Plasma Cells) may represent a *forme fruste* of classical MM and therapy may be contemplated for such patients. Up to 20% of newly diagnosed MM patients can present with renal injury, ranging from mild laboratory abnormalities through the need for renal replacement therapy (dialysis). With respect to frank MM, patients with milder renal failure may nonetheless be asymptomatic. Despite this, as renal failure can frequently be partially or fully reversible, and because of the profound implications of kidney dysfunction for both overall outcomes and options for MM disease management, new renal failure, whether at presentation or later in the disease course should be considered a medical emergency and treated promptly and aggressively in consultation with an expert nephrologist.

The most common and reversible cause of renal failure in MM is light chain tubular cast deposition and/or light chain deposition disease,[60] though monoclonal proteins may also be deposited as amyloidosis[61] (often associated with nephrotic syndrome range proteinuria) (see Chapter 93). Another common cause is hypercalcemia leading to osmotic diuresis and prerenal dysfunction associated with volume depletion—these are readily managed with intravenous volume repletion. Additional mechanisms of renal failure in MM include renal calcium deposition with interstitial nephritis, overuse of nonsteroidal anti-inflammatory drugs, hyperuricemia, chemotherapy-induced nephrotoxicity, and bisphosphonates.

Renal failure both at disease onset and during its course can significantly complicate management, as two of the three immunomodulatory drugs (lenalidomide, pomalidomide), which form the backbone of most modern therapies, are challenging or impossible to use with severe renal failure or in dialysis patients. Additionally, cytotoxic chemotherapy backbones which use cisplatin and etoposide (such as PACE [Platinol cisplatin, Adriamycin, cyclophosphamide, etoposide] or DCEP [dexamethasone, cyclophosphamide, etoposide, Platinol]) may also require therapeutically meaningful dose reductions with renal injury. Finally, because serum light chains are partially catabolized or cleared renally, in patients with kidney injury, levels of both the involved and un-involved free light chain may be elevated, and these tests must be interpreted with caution.

Anemia

Anemia, typically normocytic, is another presenting feature of myeloma. A small fraction of MM patients may present with solitary but profound anemia in the absence of other end-organ damage, and in such scenarios, a thorough evaluation including bone marrow sampling to exclude other causes of anemia is warranted. With respect to anemia secondary to PC disorders, causes are again multifactorial, including anemia of chronic inflammation, direct marrow replacement by PCs in the setting of high disease burden, paraneoplastic suppression of physiologic erythropoiesis even in patients with low marrow PC burdens, as well as inadequate erythropoietin production in patients with concomitant renal injury. After therapy with cytotoxic chemotherapy or autologous transplant, therapy-related anemia is expected and may persist, although moderate anemia can also result from treatment with novel agents, particularly in combination. Supportive management with transfusions may be initially required in newly diagnosed patients, but in most instances, disease-associated anemia is highly reversible with anti-PC therapy in the modern era and is rarely if ever a limiting toxicity when patients are treated with novel agents. Erythropoietin administration in MM patients should be used sparingly and judiciously and only in patients with renal injury, in consultation with an expert nephrologist, as significant risks are present.

Neurologic Symptoms

Patients with MM may present with a number of neurologic symptoms related either to direct involvement of the nervous system or the impact of cytokines and/or paraproteins. The most common overt abnormality is compression of the spinal cord and/or nerve roots, causing neurologic dysfunction, including paraplegia with bladder and bowel dysfunction. Cord compression is a neurologic emergency requiring urgent intervention: in this setting, spine magnetic resonance imaging (MRI) (with contrast if renal function allows) and high-dose glucocorticoids, followed by urgent radiation and/or neurosurgical intervention is generally warranted.

Peripheral neuropathy is another common manifestation and is also a key manifestation of light-chain (AL) amyloidosis (see Chapter 93). It may also develop as a result of use of a number of therapeutic agents, such as the immunomodulatory drugs (IMiDs) (most prominently thalidomide), bortezomib and ixazomib, cisplatin, and the vinca alkaloids. Anti-myelin-associated glycoprotein (MAG) peripheral neuropathy can also occur in rare cases in association with paraproteinemias. Moreover, POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes; see box on Rare Disorders Associated With Monoclonal Proteins and/or Plasma Cells) includes a prominent sensory neuropathy associated with sclerotic myeloma. As with other signs and symptoms, polyneuropathy in MM may be multifactorial, including amyloid deposits, infiltrative processes with other protein deposits, metabolic causes related to hypercalcemia and/or hyperviscosity, immune processes, or cytokines effects. Management is generally focused on treating the underlying PC disorder and minimizing further exposure to therapies with the risk of neuropathy.

Finally, although leptomeningeal disease (LMD) has traditionally been considered rare in myeloma, with the advent of novel agents and associated prolonged patient survival, this still-rare complication is nonetheless increasing in prevalence. It is a late complication of disease with no standard of care and carries a grim prognosis if present. Diagnosis can be secured with total brain and spine MRI, with and without contrast together with lumbar puncture for cytology and flow cytometry. Even more rarely, true central nervous system (CNS) intraparenchymal plasmacytomas have been reported in advanced disease – again, with no standard of care.

Hyperviscosity

Hyperviscosity in myeloma is uncommon: in general, an IgG more than 10 g/dL, IgA more than 7 g/dL, and IgM more than 5 g/dL are required to cause symptoms, and disease burdens correlated with such profound paraproteinemias would generally come to attention by manifesting other signs or symptoms. Serum viscosity can be measured to confirm hyperviscosity-associated symptoms. However, although symptomatic patients may demonstrate levels greater than 4 centipoise (cP), symptoms may also occur at lower viscosity levels. These can include headache, visual symptoms, shortness of breath, altered mental status, or an acquired bleeding diathesis associated with decreased effective levels of coagulation factor X. Therapy should be initiated more on the basis of symptomatology than on absolute measured levels of viscosity and can require prompt institution of plasmapheresis in addition to anti-PC therapy. Because of their corresponding volumes of distribution, plasmapheresis is generally more effective at rapidly resolving hyperviscosity from large pentameric IgM molecules, which are confined to the circulation, than hyperviscosity due to smaller monomeric IgG or dimeric IgA molecules.

Immune Deficiency

Infection is one of the most important causes of morbidity and a common cause of mortality in myeloma. Myeloma is associated with significant dysfunction across multiple facets of innate and adaptive immunity, with T-, B-, NK-, and myeloid-cell dysfunction all contributing to the immunodeficiency syndrome which affects both the humoral and cell-mediated immune responses. Patients with MM are at increased risk of bacterial, viral, and fungal infections and in some cases of secondary malignancies, which are a consequence of both immune dysfunction from the plasma cell disorder, as well as cytopenias and immunosuppression and the mutagenizing effects of some MM therapies. Most notably, patients receiving PIs require prophylaxis with acyclovir and valacyclovir against varicella zoster reactivation and use of cytotoxic chemotherapy combinations can be associated with prolonged periods of neutropenia, requiring growth factor support, as well as the use of prophylactic antimicrobials. With respect to steroids, the schedule and dose given in most regimens using novel agents typically does not warrant routine *Pneumocystis jirovecii* prophylaxis for the majority of patients. However, neutropenia can become a limiting toxicity of many therapeutic regimens; indeed PIs, IMiDs, and anti-CD38 monoclonal antibody therapy as well as a number of agents used late in treatments such as panobinostat and selinexor can all be associated with neutropenia—an individualized approach to antimicrobial prophylaxis may be required. Finally, with effective anti-PC therapy, most patients develop hypogammaglobulinemia. However, routine IVIG administration in the absence of recurrent infections is not a common practice for most practitioners who treat MM.

Coagulation Disorders

Coagulation abnormalities are observed in MM patients and can be a consequence of treatment. A disease-related hypercoagulable state is observed in many patients, secondary to hyperviscosity, acquired activated protein C resistance, lupus-like anticoagulants with thromboembolic complications, acquired protein S deficiency, and a therapy-related hypercoagulability associated specifically with the use of IMiDs. As with other cancers, venous thromboembolic events dominate over arterial clots. Given this, aspirin or direct oral anticoagulant prophylaxis (factor Xa inhibitors) is routine when patients are prescribed IMiD-based therapeutic regimens, and a high index of suspicion is warranted for patients who present with potential clinical signs or symptoms consistent with venous thromboembolism. Although in newly diagnosed patients, thrombocytosis is more frequently associated with myeloma than thrombocytopenia, as a consequence of extensive bone marrow infiltration by myeloma cells, and more commonly repeated cycles of chemotherapy over multiple lines of treatment, patients may become significantly thrombocytopenic during the advanced stages of disease. The dangers of bleeding tendency in combination with weakness and debility and the potential for falls and traumatic injury in advanced patients is particularly worrisome. Furthermore, much like neutropenia, thrombocytopenia can become a dose-limiting toxicity for effective disease-directed therapy, particularly in later lines.

Amyloidosis

Monoclonal proteins, specifically light chains, can be deposited in various organs as an insoluble fibrillar protein, amyloid, affecting organ dysfunction (see Chapter 93). Around 5% to 20% of patients with AL amyloidosis also have a concurrent diagnosis of MM, and by definition, all patients with AL amyloid have clonal light-chain production. Although clinically overt amyloidosis is observed less frequently in MM, intense investigation to identify amyloid deposits using fat pad biopsies (for immunohistochemistry, electron microscopy, or mass spectrometry), concurrent staining of bone marrow with Congo Red, and obtaining biopsies of other tissues (such as the GI tract) can identify some level of amyloid deposit in almost one-third of such patients. Identification of cardiac amyloidosis can have implications for treatment planning in MM patients with respect to use of regimens with potential cardiotoxicity, such as carfilzomib, and screening patients with cardiac troponins, B-type natriuretic peptide (BNP), or N-terminal pro-B-type natriuretic peptide (NT-proBNP) is recommended. EKG as well as both echocardiogram and cardiac MRI (to demonstrate an infiltrative cardiomyopathy) may be helpful non-invasive modalities which can suggest cardiac amyloidosis. Patients with both amyloid deposits and MM can present with a number of features primarily related to organ damage, including renal and cardiac dysfunction and neuropathy. Such patients may be challenging to treat, but therapeutic intervention is generally similar to those with MM without amyloidosis, with the necessary concessions to modifications of regimens for cardiomyopathy, renal dysfunction, etc.

Laboratory and Radiologic Studies for the Diagnosis and Monitoring of Multiple Myeloma and Related Entities

A thorough diagnostic evaluation is required to secure the diagnosis of MM and to assess for disease sequelae and organ dysfunction, related to the plasma cell neoplasm or otherwise. The findings can have significant impact on the precise entity diagnosed (e.g., MM vs. solitary plasmacytoma), disease risk stratification and associated selection of appropriate treatment regimens, and of course patient counseling and prognostication. A number of investigations are also useful to assess for treatment response and to restage patients after therapy. For a summary of the workup of new patients, see box on Investigations for Patients Suspected or Confirmed to Have Newly Diagnosed Multiple Myeloma.

Investigations to Detect Clonality

Protein Electrophoresis

Serum protein electrophoresis is performed for screening, and to quantitate the monoclonal proteins present in plasma cell disorders (see box on Investigations for Patients Suspected or Confirmed to Have Newly Diagnosed Multiple Myeloma). In approximately 70% of the patients, the monoclonal protein is IgG; in 20%, it is IgA; and in 5% to 10% of patients, it is light chains only without an intact immunoglobulin molecule. Less than 1% of patients have a monoclonal protein that is IgD, IgE, or IgM or even more rarely, a true nonsecretory myeloma. The identification of the precise paraprotein(s) in both serum and urine currently requires immunofixation (Fig. 91.4), and this test should always be paired with protein electrophoresis studies. Of note, because of the rarity of clonal IgD and IgE disorders, immunofixation studies do not routinely assess for IgE or IgD paraproteins; on initial evaluation for a new patient, measurement of total serum levels of IgE and IgD is recommended.

INVESTIGATIONS FOR PATIENTS SUSPECTED OR CONFIRMED TO HAVE NEWLY DIAGNOSED MULTIPLE MYELOMA

Studies of Blood

- Complete blood count with differential
- Comprehensive metabolic panel and GFR calculation
- Magnesium
- Phosphorus
- Serum protein electrophoresis
- Serum immunofixation electrophoresis
- Serum free light chains and ratio
- Quantitative IgG, IgM, IgA, IgD, IgE
- Lactate dehydrogenase
- β_2 microglobulin
- Erythrocyte sedimentation rate
- C-reactive protein
- Additional studies:
  - Type and screen, if patient will require transfusions (notify laboratory if daratumumab planned)
  - Serum viscosity if M-spike is extremely large, or concerned for hyperviscosity symptoms
  - VEGF and hormone studies (TSH, free T4, serum cortisol, sex hormone levels) if concerned for POEMS
  - Serum coagulation factor X and cardiac biomarker evaluation if concerned for AL amyloidosis (see also *cardiac markers*, below)

Urine Studies

- 24 urine collection for:
- Total protein
- Total creatinine and creatinine clearance
- Protein/creatinine ratio
- Urine free light chains
- Urine immunofixation electrophoresis

Unilateral Marrow Sampling

- Bone marrow biopsy and aspirate
  - Plasma cell percentage (highest as determined by biopsy, aspirate, or flow cytometry)
  - Plasma cells are quantified by morphology on an aspirate smear, typically by counting 100–200 consecutive cells
  - Plasma cells are quantified by CD138 immunohistochemistry on core biopsy; this percentage is typically the highest of the three studies
  - By flow cytometry, plasma cells (by characteristic cell surface markers and/or light chain restriction) as a percentage of total white blood cells is calculated; flow cytometry drastically underestimates the percentage in nearly all cases
- Demonstration of clonality: κ and λ light chain restriction (excess), typically with immunostaining on core biopsy, or intracellular light chain studies by flow cytometry. An aberrant flow cytometric cell surface phenotype may also suggest
- Genomic profiling by next-generation sequencing (NGS) or other assays as available, performed on $CD138^+$ enriched cells from an aspirate sample, including as a minimum the following validated markers of high-risk disease:
  - Translocations of *IGH* (chromosome 14) with a number of partners
    - t(4;14) – *MMSET*
    - t(11;14) – *CCND1*
    - t(14;16) - *MAF*
    - t(14;20) – *MAFB*
  - Chromosome 17p deletion (loss of *TP53*)
  - Chromosome 1q gains
  - Somatic mutation analysis of *TP53*
- Baseline profiling of tumor cells for MRD tracking by flow cytometry and/or NGS-based assays
  - Flow cytometry: per local guidelines (not mandatory)
  - NGS: immunoglobulin gene sequencing mandatory
- Additional studies:
- Congo Red staining if suspecting amyloid
- Gene expression profiling or extended genomic sequencing (investigational)
- Banking of marrow samples for clinical trials, including subsequent assessment of BCMA, GPRC5D, etc.

Imaging Studies

- 18F-FDG/PET with associated low dose CT
- Total body MRI without contrast—if not available, total spine and pelvis MRI is sufficient

Note: there is no role for plain film skeletal survey in the evaluation of patients in practice scenarios where MRI and/or PET/CT are available.

Cardiac Studies

- EKG
- Troponin T or I
- BNP, NT-proBNP
- Consider echocardiogram if symptomatic, prior cardiac history, ruling out AL amyloidosis, or using carfilzomib-based therapy
- Consider cardiac MRI in consultation with cardiologist, if high suspicion for amyloidosis

Tissue Biopsy

- Abdominal fat pad biopsy, if ruling out AL amyloidosis. Possible studies to identify amyloidosis include immunohistochemistry, electron microscopy, and/or mass spectrometry

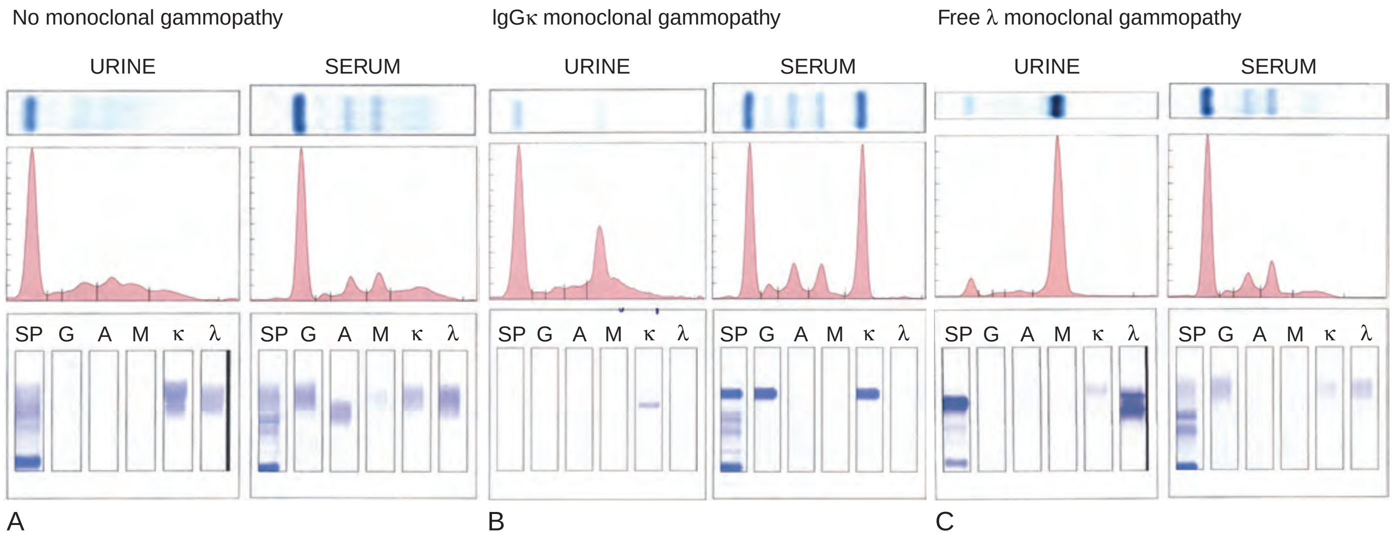

Figure 91.4 REPRESENTATIVE PATTERNS OF SERUM PROTEIN ELECTROPHORESIS AND IMMUNOFIXATION ELECTROPHORESIS. In each figure, the *upper panels* represent immunofixation patterns, the *middle panels* are the densitometric tracings of the gels, and the *lower panels* are agarose gels of urine sample *(left)* and serum *(right)*. (A) Normal pattern of serum and urine protein on electrophoresis. Because there are many different immunoglobulins in the serum, their differing mobilities in an electric field produce a broad peak. (B) In monoclonal gammopathies, the predominance of a product of a single cell produces a sharp peak. The immunofixation identifies the type of immunoglobulin, such as κ light chain in urine and IgGκ in serum. (C) In patients with light chain–only disease, a clonal band is observed only in urine, with no clear peak in serum, such as γ light chain in urine with no distinct immunofixation positivity in serum. *(Courtesy Dr. Neal I. Lindeman; used with permission.)*

As noted above, patients who produce intact immunoglobulins can also produce excess free light chain; for example, a patient's PCs can secrete an intact IgG κ protein as well as free κ light-chains. Notably, in such cases, with the selection pressures of anti-myeloma therapy, sequential evaluation may reveal a predominance of either the intact immunoglobulin or the light chain as the disease biomarker (e.g., only IgG κ, or only a κ light-chain myeloma—the so called "light chain escape" phenomenon).

Finally, the presence of a monoclonal protein can cause "reciprocal" suppression of levels of the uninvolved immunoglobulins. This can be observed both in precursor states such as SMM as well as MM: for example, patients with IgG myeloma can have suppressed IgA and IgM. In newly diagnosed patients if all three immunoglobulins are suppressed, one should suspect either light-chain disease and/or the possibility of IgD or IgE or even true nonsecretory MM, although light chain disease is the far more common entity. More notably, suppression of all three immunoglobulins is common with successful anti-PC therapy. More rarely, a biclonal or triclonal pattern of immunoglobulins is observed, more often with the same light chain but rarely with a different heterotypic light chain. This may suggest truly separate clones, especially if distinct (κ vs. λ) light chains are seen. In other rare clinical instances, a PC neoplasm may co-exist in the same patient with an indolent B cell lymphoma (clonally related or otherwise), which may also secrete paraproteins, leading to unusual electrophoresis results.

Quantitation of Bence Jones proteins in urine is still important, both for diagnosis of myeloma and for follow-up. However, it is important to note that quantitative free light-chain measurements or ratios in the urine is rarely informative. Rare patients with a monoclonal protein detectable only in the urine but no paraproteinemia in the blood, may require more frequent 24-hour urine collections during treatment and follow-up.

Therapeutically, MM patients with each of the various types of immunoglobulins are treated with the identical therapy at present; however, IgA myeloma was previously associated an inferior survival for a given level of blood proteinemia. This has been attributed to more rapid catabolism and turnover of serum IgA, such that an equivalent numeric level of serum IgA relative to monoclonal IgG may reflect a higher total disease burden.

The immunoglobulin isotype remains constant in a given patient over the natural history of the disease; however, occasionally, a patient producing one immunoglobulin at the time of diagnosis, at relapse, or with advanced disease may present with only the same light chain as initially observed with the original immunoglobulin (light chain escape) or more rarely may become "hyposecretory" (with aberrantly low paraprotein levels for the actual total body disease burden) or even truly nonsecretory. Such changes are believed to reflect changes in neoplastic plasma cells to a more aggressive or undifferentiated form. As a result of the observed light-chain escape, such patients without Bence Jones proteins initially detected in the urine can require periodic 24-hour urine Bence Jones protein measurements during follow-up.

Finally, although not directly evaluated by electrophoresis or immunofixation, the unique genetic sequences that are observed with the idiotype of each paraprotein (the third complementarity determining region (or CDR3) have been used as a marker that specifically identifies a tumor cell clone and have been applied to next generation sequencing (NGS) or allele-specific oligo-polymerase chain reaction (PCR)—based methodology to detect MRD with high sensitivity (see Minimal Residual Disease).

Serum Free Light Chains

This test specifically measures serum light chains that are *not* associated with heavy chains, i.e., those that are not part of an intact immunoglobulin molecule (Fig. 91.5). The presence of excess serum free light chains provides an additional marker and measurement of plasma cell burden, and its quantitation has been used to assess disease burden levels in a number of patients who were previously considered oligosecretory or nonsecretory. For example, up to 80% of patients with the previous label of "nonsecretory myeloma" actually have measurable serum free light chains.[62] Routine use of serum free light chain measurements is indicated for diagnosis, response evaluation, and prognosis in essentially all patients.

Bone Marrow Examination

Except for patients with solitary plasmacytoma, the presence of clonal plasma cells (>5%) is usually observed in all plasma cell disorders starting with MGUS up through MM, with the phenotype of malignant plasma cells generally distinguished from normal plasma cells by monoclonal antibody staining and flow cytometry (Table 91.2).[63–65] Clonal plasma cell populations comprising 10% or greater of the nucleated cells within a bone marrow aspirate or biopsy (whichever is higher) are required to differentiate MGUS from SMM and for the diagnosis of MM (Table 91.3). The quantitation of plasma cells should be performed with at least a 200-cell count on aspirate smear, and confirmation of clonality is essential for diagnosis, which can be done either by immunostaining using κ/λ staining on core biopsy for excesses of PCs expressing κ or λ, or alternatively by flow cytometry for intracellular light chain restriction and/or the expression of aberrant cell surface proteins (Fig. 91.6 and box on Investigations for Patients Suspected or Confirmed to Have Newly Diagnosed Multiple Myeloma). In the absence of clear bone marrow involvement, a

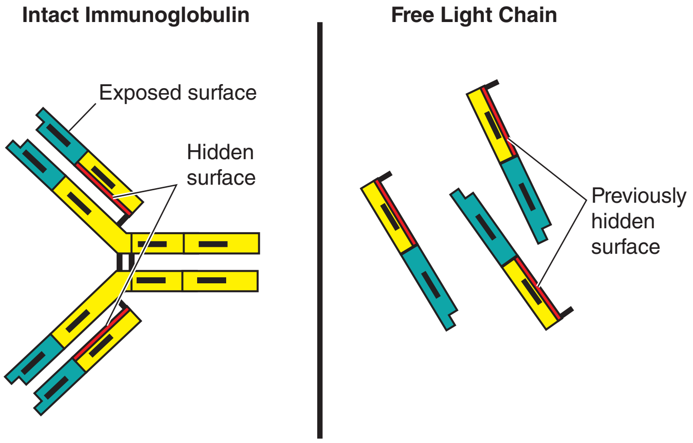

Figure 91.5 PRINCIPLE FOR MEASUREMENT OF FREE LIGHT CHAINS. The free light chain assay measures light chains on the basis of a part of the light chain molecule which is hidden when the light chains are in complex with heavy chains as part of an intact immunoglobulin molecule *(left)*. This hidden surface is exposed when light chains circulate as free proteins, allowing their specific measurement *(right)*.

TABLE 91.2 Phenotypic Characterization of Plasma Cells

Adhesion Molecule	Normal Plasma Cells	Multiple Myeloma Cells
CD138	+	+
CD19	+	–
CD28	–	–
CD38	+	+
CD40	+	+[a]
CD45	+	–[b]
CD27	–	+
CD11a	+	–
CD11b	–	–
CD44	+	+
CD54	+	+
CD56	–	+
CD58	–	+
LFA-1	–	–/+
RHAMM	–	+
VLA-4	+	+
VLA-5	+	+

[a] CCD40 expression is enhanced on plasma cell leukemia cells relative to normal plasma cells and MM cells.
[b] CD45 on immature myeloma cells.
LFA-1, Lymphocyte function-associated antigen 1; *MM*, multiple myeloma; *RHAMM*, receptor for hyaluronan-mediated motility; *VLA-4*, very late antigen 4; *VLA-5*, very late antigen 5.

TABLE 91.3 Diagnostic Criteria for Multiple Myeloma, Myeloma Variants, and Monoclonal Gammopathy of Unknown Significance

Monoclonal Gammopathy of Undetermined Significance (MGUS) or Monoclonal Gammopathy, Unattributed/Unassociated (MG[u])
M protein in serum <30 g/L
Bone marrow clonal plasma cells <10%
No evidence of other B-cell proliferative disorders
No myeloma-related organ or tissue impairment (no end-organ damage, including bone lesions)
Asymptomatic Myeloma (Smoldering Myeloma)
M protein in serum >30 g/L and/or
Bone marrow clonal plasma cell ≥10%– 60%
No related organ or tissue impairment (no end-organ damage, including bone lesions) or symptoms
Symptomatic Multiple Myeloma
M protein in serum and/or urine[a]
Bone marrow (clonal) plasma cells[a] or plasmacytoma
Related organ or tissue impairment (end-organ damage, including bone lesions)
Bone marrow clonal plasma cells >60%
Involved/Uninvolved light chain ratio >100, with the involved light chain >100 mg/L
More than one characteristic lesion in the bone or bone marrow by MRI
Solitary Plasmacytoma of Bone
No M protein in serum and/or urine[b]
Single area of bone destruction caused by clonal plasma cells
Bone marrow not consistent with MM
Normal skeletal survey (and MRI of spine and pelvis if done)
No related organ or tissue impairment (no end-organ damage other than solitary bone lesion)[b]
Nonsecretory Myeloma
No M protein in serum and/or urine with immunofixation
Bone marrow clonal plasmacytosis ≥10% or plasmacytoma
Related organ or tissue impairment (end-organ damage, including bone lesions)
Extramedullary Plasmacytoma
No M protein in serum and/or urine[c]
Extramedullary tumor of clonal plasma cells
Normal bone marrow
Normal skeletal survey
No related organ or tissue impairment (end-organ damage including bone lesions)
Multiple Solitary Plasmacytomas (Recurrent or Not)
No M protein in serum and/or urine[d]
More than one localized area of bone destruction or extramedullary tumor of clonal plasma cells that may be recurrent
Normal bone marrow
Normal skeletal survey and MRI of spine and pelvis if done
No related organ or tissue impairment (no end-organ damage other than the localized bone lesions)
Myeloma-Related Organ or Tissue Impairment (End-Organ Damage)
Calcium levels increased: serum calcium >0–25 mmol/L above the upper limit of normal or >2–75 mmol/L
Renal insufficiency: creatinine >173 mmol/L (>2 mg/dL)
Anemia: Hemoglobin 2 g/dL below the lower limit of normal or hemoglobin <10 g/dL
Bone lesions: Lytic lesions or osteoporosis with compression fractures (MRI or CT may clarify)
Other: Symptomatic hyperviscosity, amyloidosis, recurrent bacterial infections (more than two episodes a year)

CT, Computed tomography; *MRI*, magnetic resonance imaging.
[a] If flow cytometry is performed, most plasma cells (>90%) will show a neoplastic phenotype.
[b] A small M component may sometimes be present.
[c] A small M component may sometimes be present.
[d] A small M component may sometimes be present.

biopsy-proven soft tissue or bony plasmacytoma is also adequate for diagnosis (Fig. 91.7). Genomic profiling of $CD138^+$ enriched marrow aspirate samples should be performed at the time of diagnosis and may also need to be repeated at the time of relapse or progression. Of note, although important for prognostication in MM, genomic abnormalities *do not* differentiate MM from precursor states and are also currently not predictive of response to therapy in the up-front setting. Eight to ten-color flow cytometry panels are now also used with bone marrow samples to detect MRD,[65] and establishment of the initial cell-surface phenotype at diagnosis can be important if flow-cytometry based MRD monitoring is elected. Baseline characterization of immunoglobulin gene sequences is mandatory for NGS-based MRD tracking.

Investigations to Detect End-Organ Damage

The diagnosis of a plasma cell disorder is based on the presence of a monoclonal protein and clonal plasma cells. However, the diagnosis of MGUS/SMM, for which there is currently insufficient evidence to warrant therapeutic intervention, versus active symptomatic MM,

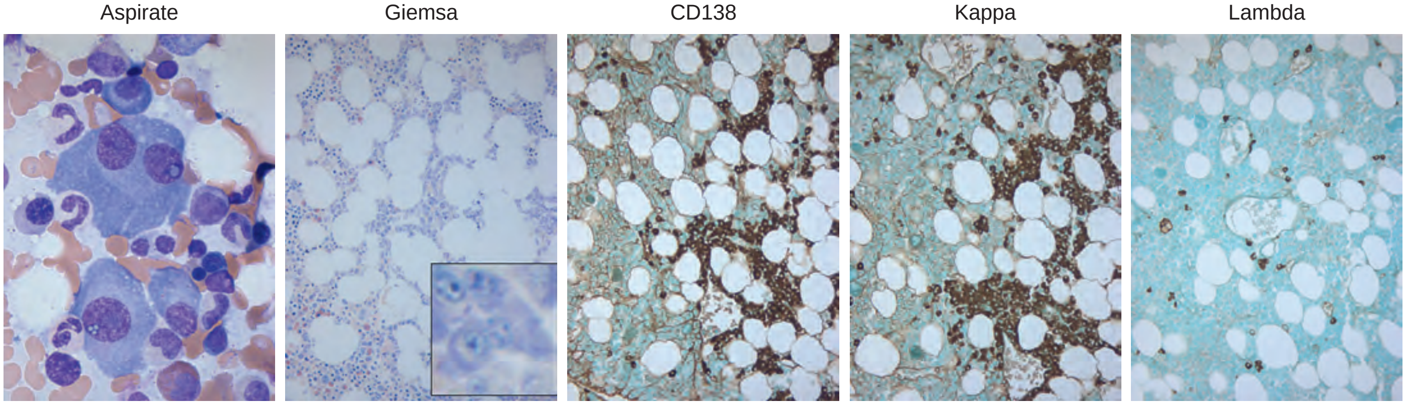

Figure 91.6 BONE MARROW EXAMINATION FROM A PATIENT WITH IGG κ MYELOMA, SHOWING NEOPLASTIC PLASMA CELLS. The cells are CD138$^+$, and κ light chain–positive but λ-negative. *(Courtesy Dr. Ruben Carrasco, M.D.; used with permission.)*

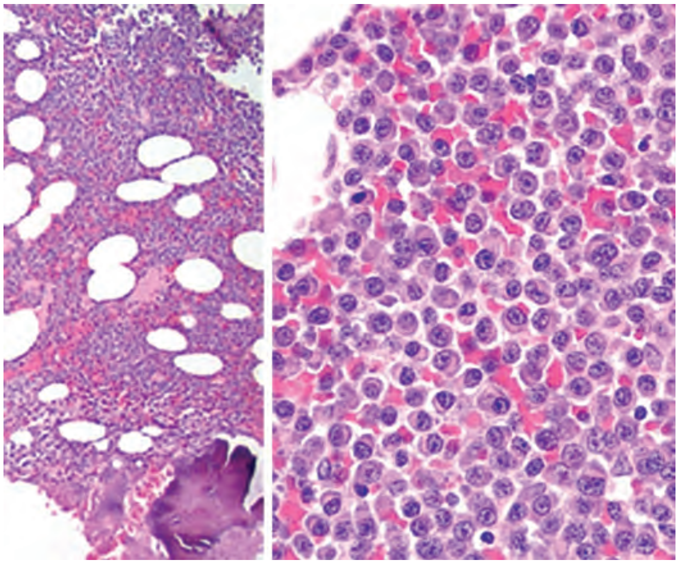

Figure 91.7 MORPHOLOGY OF NEOPLASTIC PLASMA CELLS IN MULTIPLE MYELOMA. There is significant morphologic heterogeneity in the plasma cells, as seen on bone marrow biopsy.

which needs treatment, is largely predicated on the demonstration of end-organ damage, which includes bone lesions, anemia, renal dysfunction, and hypercalcemia. The details of the diagnostic criteria are listed in Table 91.3 and diagnostically useful tests can be found in the box on Investigations for Patients Suspected or Confirmed to Have Newly Diagnosed Multiple Myeloma.

Radiographic Evaluation

Skeletal evaluation is mandatory in the workup of patients with possible MM. Arguably the previous standard for evaluation of bone lesions, the whole body plain X-ray skeletal survey has been supplanted by 18F-FDG-PET (fluorodeoxyglucose-positron emission tomography) combined with low-dose whole body computed tomography (CT), or total body (occasionally total spine and hip) MRI without contrast due to markedly improved sensitivity and specificity in clinical practice settings where these advanced imaging modalities are available.[66,67] The presence of characteristic bony lytic lesions is considered diagnostic for myeloma (Fig. 91.8). Of note, although useful for assessing disease burden and location at the time of initial diagnostic workup, bone lesions do not always resolve following effective therapy, although if patients are followed by serial positron emission tomography (PET) imaging, there is oftentimes resolution of FDG avidity. Given this, cross-sectional imaging is frequently most useful for initial assessment and restaging and at time of disease progression, rather than for response assessment per se. Lastly, because of the absence or suppression of osteoblastic activity and therefore lack of radiotracer uptake, the bone scan is generally not a useful investigative tool in myeloma. Details of various imaging modalities and their role in myeloma diagnostics are summarized in Table 91.4.

Indeed, based on superior test performance characteristics, MRI, CT, and PET are increasingly being used for patients with MM. In particular, MRI[68] without contrast is a useful modality. In the initial diagnostic workup of patients with overlap syndromes which span indolent lymphomas vs. MM, modern MRI protocols can allow for assessment of lymphadenopathy and organomegaly, while also allowing for detailed evaluation of the degree of bone marrow involvement and involvement of the spinal cord. Note that even in the absence of frank lytic bone disease, the presence of two or more characteristic marrow-based lesions each at least 5 mm in diameter is consistent with MM. Moreover, MRI is indicated in all patients with a suspected diagnosis of a solitary plasmacytoma and is indicated in patients with putative SMM to exclude any occult bone or marrow involvement. Finally, in the rare patient with true nonsecretory myeloma, MRI without contrast is an important tool for response evaluation and assessing disease burden, as it is a noninvasive modality that facilitates serial imaging without concerns for cumulative radiation exposure or other toxicities.

CT scanning, typically not involving the use of contrast, has also been used to localize focal lesions for tissue biopsy. CT scanning has superior sensitivity and specificity for lytic bone disease as compared with plain film skeletal series and may be superior for imaging of the hard bone itself relative to MRI, although the bone marrow cannot be usefully evaluated. In areas where 18F-FDG-PET scanning is available, many practitioners combine low-dose CT with PET. Combined PET/CT can be used to define extramedullary disease (EMD) as well as medullary lesions, and also complement MRI for follow-up of patients with nonsecretory myeloma (Fig. 91.9). Conversion of target lesions from 18F-FDG-PET positivity to negativity with effective locoregional or systemic therapy, as appropriate, also has prognostic significance. A prospective evaluation of MRI and PET/CT at diagnosis and before maintenance therapy was performed in a subgroup of 134 patients with MM in the IFM/DFCI 2009 trial. At diagnosis, MRI was positive in 127 (94.7%) of 134 patients and PET-CT was positive in 122 (91%) of 134 patients, respectively ($P = .33$). Few patients achieved a normal MRI after 3 cycles of VRD before maintenance. Normalization of the MRI following 3 cycles of VRD and before maintenance was not predictive of both progression-free survival (PFS) and OS. Normalization of PET/CT was more frequently observed: 45% following 3 cycles of VRD and 79% before maintenance. Importantly, normalization of PET-CT was associated with an improvement in PFS, and normalization before maintenance was a predictor for improved OS.

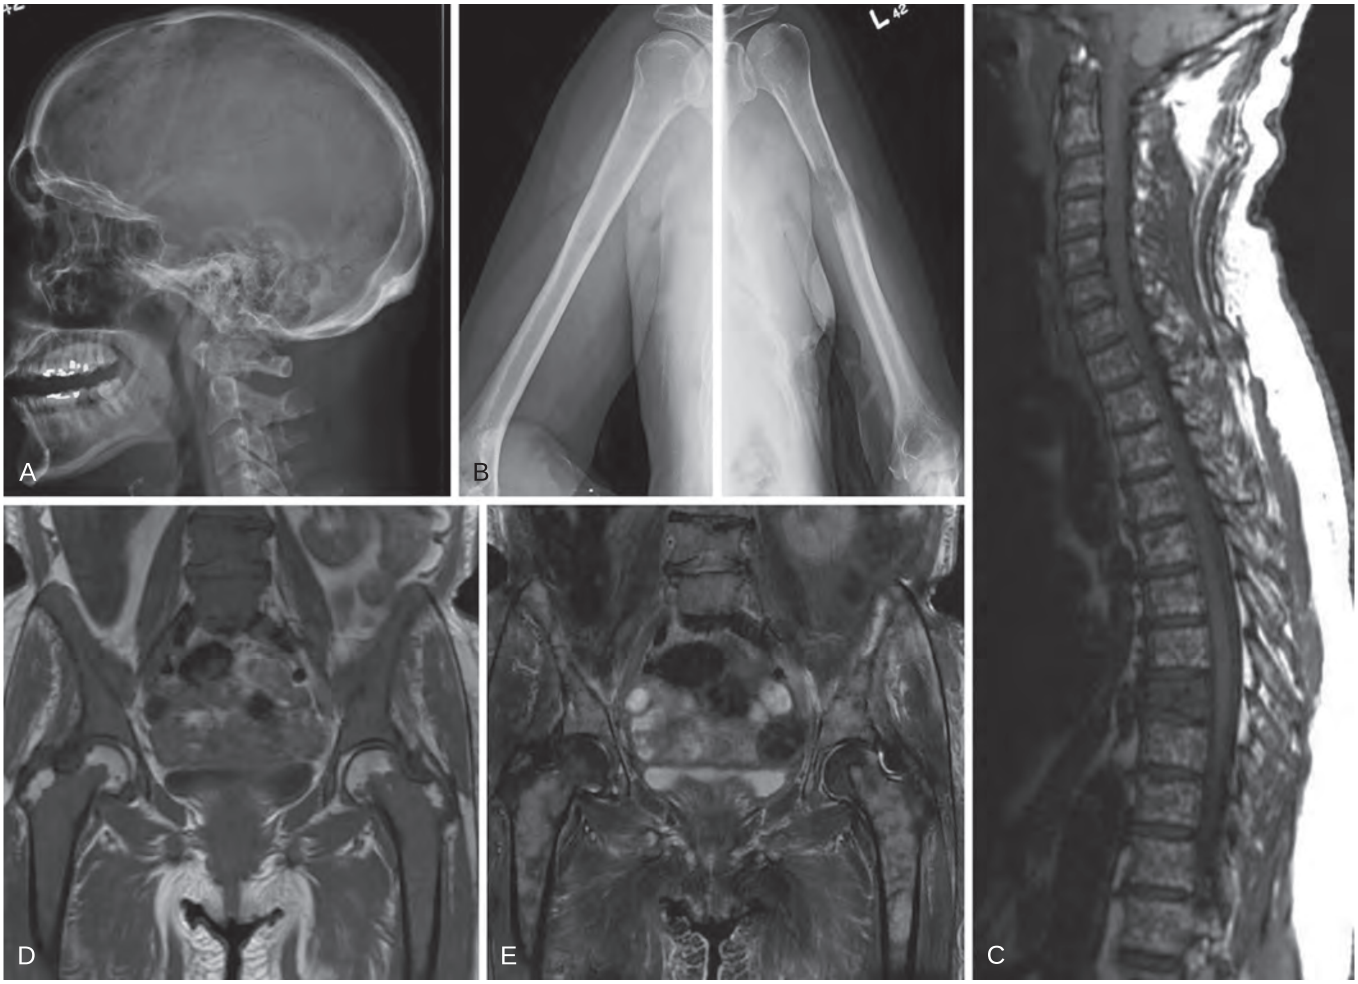

Figure 91.8 TYPICAL SKELETAL CHANGES OF MULTIPLE MYELOMA. (A, B) Examples of "punched-out" lytic lesions in skull and humerus. (C–E) Magnetic resonance imaging pattern in multiple myeloma in spine and pelvis showing diffuse involvement with focal lesions.

TABLE 91.4 Imaging Modalities for Disease Assessment in Myeloma

	Use	Sensitivity/Specificity	False-Negatives	False-Positives
Bone scan	• For diagnostic screening, except for multiple myeloma	Varies	Pure osteolytic lesions	• Trauma • Inflammation • Benign tumor • Healing
X-ray	• Can clarify nonspecific findings on bone scan • Assesses risk of fracture • Possible follow-up of tumor response, but evidence of response takes considerable time to appear	Low sensitivity	Low disease burden Osteopenia	• Trauma • Inflammation • Benign tumor • Healing
CT	• For anatomic detail in axial skeleton • Possible follow-up of tumor response, but role is still undefined	High sensitivity	Low disease burden	• Trauma • Inflammation • Benign tumor • Healing
MRI	• Detection of spinal cord compression • Can help distinguish benign from malignant vertebral compression fracture • Possible follow-up of tumor response, but role is still undefined	High sensitivity and specificity	Lesion only in cortex	• Edema
PET scan	• May eventually become first-line screening test for bone metastases • Possible follow-up of tumor response, but role is still undefined	High specificity	Lesion only in cortex	• After chemotherapy
Bone density	• Measure osteoporosis • Response to bisphosphonates	High specificity and sensitivity		• Age-related osteoporosis

CT, Computed tomography; *MRI*, magnetic resonance imaging; *PET*, positron emission tomography.

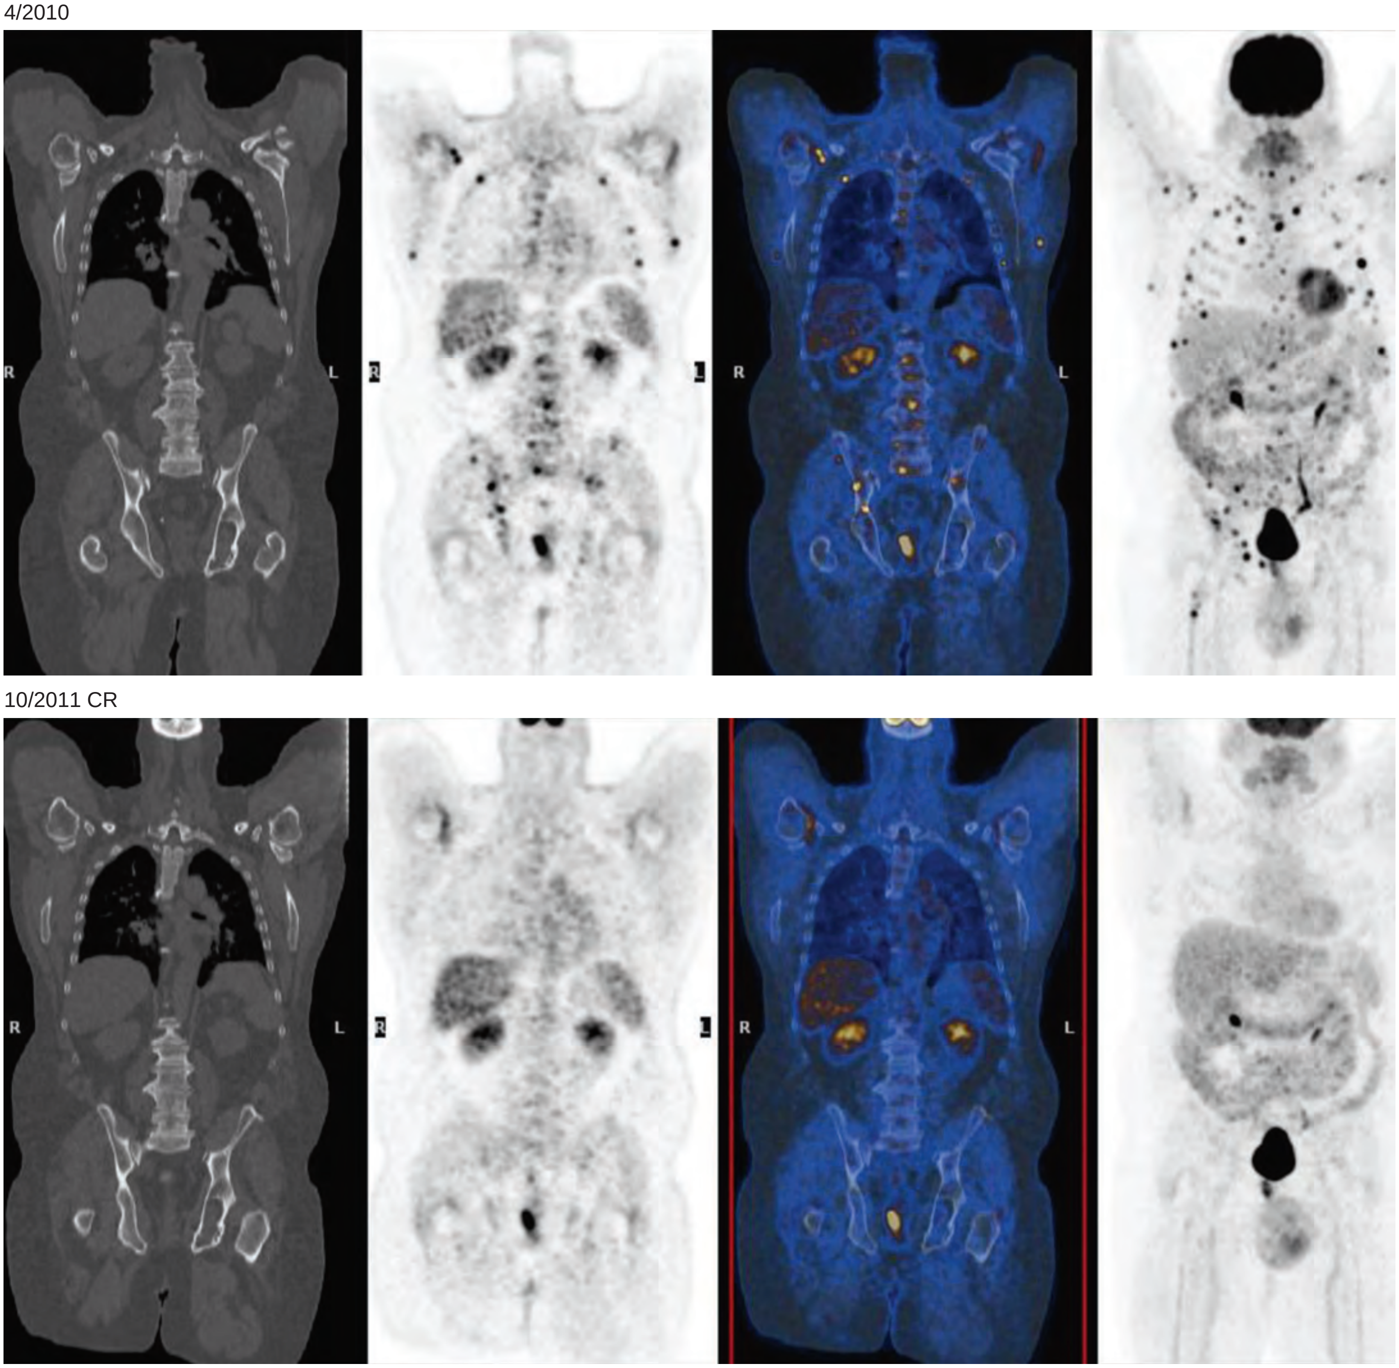

Figure 91.9 POSITRON EMISSION TOMOGRAPHY / COMPUTED TOMOGRAPHY SCANS IN MULTIPLE MYELOMA. Upper panels show multiple 18F-fluorodeoxyglucose (FDG)-avid lesions throughout the skeleton. The lower panels show their resolution at the time of achieving complete remission.

Renal Function

A serum creatinine greater than 173 mmol/L (2 mg/dL) is considered to represent end-organ damage from myeloma. However, as absolute creatinine values do not incorporate the patient's age, race, or body mass, they may under- or over-represent the extent of renal dysfunction. Conversely, because patients with myeloma are older and may have other comorbidities such as diabetes and hypertension which can also impair renal function, it may be necessary to establish the causal relationship between renal dysfunction and the plasma cell disorder. This is particularly critical in patients who would otherwise be classified as MGUS or SMM but have renal dysfunction. In the majority of cases, a 24-hour urine collection with analysis of creatinine, total protein, and identification of paraproteins in the urine is sufficient. However, a renal biopsy in consultation with an expert nephrologist can occasionally be required when the clinician is truly is uncertain about the cause of the renal dysfunction. On the other hand, patients who present with renal impairment but also other manifestations of myeloma end-organ damage primarily require careful monitoring and optimization of kidney function. In such a scenario precise diagnostic workup to assign attribution of the precise subtype of PC-associated pathophysiologic process causing renal injury rarely causes changes in management.

Blood Counts and Serum Calcium

A standard complete blood count with differential is performed to detect anemia. The level of anemia considered diagnostic of myeloma is a hemoglobin 2 g/dL below the lower limit of normal or the patient's baseline level or hemoglobin <10 g/dL. It is always necessary to exclude other causes of anemia, especially in the elderly population where MM is more common. The white blood cell differential is important for assessing primarily neutropenia or thrombocytopenia secondary to disease or treatment, although in some cases circulating plasma cells may also be observed on automatic or manual differential count. Likely because of their strong dependence on the microenvironment in general, circulating plasma cells are infrequently observed in patients with MM. If present even at low level in the blood that do not meet criteria for plasma cell leukemia (PCL), this finding is associated with a poor prognosis.[69,70] A serum calcium level should be measured and corrected to the level of albumin. An ionized calcium level can sometimes be useful, particularly in patients receiving therapy for hypercalcemia.

Ancillary Studies

As part of initial evaluation, serum IgD and IgE levels are useful in order to screen all patients for rare cases of myeloma secreting these immunoglobulins, as serum or urine immunofixation electrophoresis does not routinely assess for monoclonal IgD or IgE. Lactate dehydrogenase (LDH) and serum β_2 microglobulin levels are useful measures of disease burden and required for accurate use of the revised international staging system (R-ISS). For patients who present with hypercalcemia, ionized calcium, an intact PTH, PTH related peptide, 25-OH vitamin D and 1,25-$(OH)_2$ vitamin D levels, as well as 24-hour urine calcium studies, may be helpful if there is diagnostic uncertainty about the etiology of hypercalcemia.

EKG, cardiac troponin T or I, BNP, and/or NT-proBNP are useful at diagnosis to screen for cardiac amyloidosis as well as to assess baseline cardiac function in anticipation of therapy, especially if use of agents with potential cardiac toxicities, such as carfilzomib or anthracycline containing c chemotherapy regimens are anticipated. A coagulation factor X level can be useful if assessing coagulopathy secondary to AL amyloidosis. For selected patients where POEMS is suspected or diagnosed, a VEGF level, and endocrine studies (e.g., thyroid stimulating hormone (TSH), free T_4, adrenocorticotropic hormone (ACTH), cortisol, sex hormone studies) may have utility at diagnosis and during follow-up. Finally, in our practice, we routinely check the erythrocyte sedimentation rates (ESR) and C-reactive protein (CRP) levels in newly diagnosed patients.

Although tumor lysis syndrome is rare it has been observed with effective myeloma therapy in both the newly diagnosed and relapsed/refractory settings. Measurement of uric acid levels and a glucose-6-phosphate dehydrogenase screen (for rasburicase therapy if needed) should be considered in patients judged to be at high risk for developing tumor lysis syndrome, although routine pharmacologic tumor lysis prophylaxis is not generally warranted for most patients.

Minimal Residual Disease

Minimal (or measurable) residual disease (MRD) testing refers to dynamic assessment of the tumor mass remaining after treatment and during follow-up. Current International Myeloma Working Group (IMWG) guidelines define MRD negativity as fewer than one tumor cell in 100,000 bone marrow cells (10^{-5}) as assessed by flow cytometry or NGS in a patient who fulfills the conventional criteria for a complete response.[71] Achieving MRD negativity has been established as a strong prognostic biomarker in several recent meta-analyses (Table 91.5).[72,73] Indeed, becoming MRD negative more strongly affects MM PFS than which therapeutic regimen was used to get there, as evidenced by recent randomized clinical trials in the newly diagnosed setting (Fig. 91.10)[74,75] and relapse setting.[76–78] Furthermore, in these studies, MRD status had a stronger impact on PFS than conventional biomarkers of high-risk disease such as the International Staging System (ISS), t(4;14), and del(17p), raising the possibility that MRD status may be used prospectively to guide treatment.[77,79] Investigators from the University of Arkansas have followed over 600 patients treated with Total Therapy–type regimens (described in the Treatment section) who were MRD-negative to a depth of 10^{-5} by flow cytometry for a median of 10 years, with serial MRD assessment.[80] In this population, 60% of patients achieved sustained MRD negativity, with the remaining 40% converting to the MRD positive state on average 5.7 years after high dose chemotherapy and autologous stem cell transplant (ASCT). Conversion to MRD positivity was associated with inferior PFS and OS, as has been observed in other studies. These data are similar to results of phase II data with combinations of novel agents such as KRd (carfilzomib, lenalidomide, dexamethasone), where the median duration of MRD negativity was also close to 5 years[81] in one series, with an arguably significantly less toxic modern regimen. The duration of sustained MRD negativity with modern therapies is likely to be an area of continued investigation and may be one yardstick to measure their efficacy as the PFS and OS of MM patients continues to lengthen.

There have been considerable advances in MRD testing since the latest IMWG criteria were developed in 2014. Recent studies using highly sensitive assays have demonstrated a dose-response relationship between the concentration of residual tumor cells and patient outcomes.[79,82] The strongest impact on PFS was seen with a sensitivity of

TABLE 91.5 Association of Minimal Residual Disease Status With Progression-Free Survival and Overall Survival

Study	Design	MRD Testing Strategy	N (PFS)	N (OS)	PFS Benefit, HR (95% CI)	PFS Benefit, Median	OS Benefit, HR (95% CI)	OS Benefit, Median

Figure 91.10 The association of minimal residual disease *(MRD)* negative status with outcomes from the IFM/DFCI 2009 trial. MRD status is a stronger predictor of disease progression than the treatment modality to which patients were exposed (i.e., transplant vs. no-transplant).

10^{-6}, which is the highest that can be achieved with current methods. Higher sensitivity than 10^{-6} may be technically possible but is practically limited by the number of bone marrow cells available for analysis (e.g., a sensitivity of 10^{-6} requires at least 3 million cells; 10^{-7} would require 30 million). Based on current data, there is strong evidence that 10^{-6} should be the future standard for MRD negativity in the bone marrow; MRD testing with a sensitivity of 10^{-4} or lower is not to be informative.

The optimal time to test for MRD in the bone marrow during the course of treatment depends on the dynamics of response to a particular therapeutic strategy. Historically, MM therapies resulted in gradual reduction of tumor burden over the course of several months, mirroring the slow clearance of serum monoclonal immunoglobulins (the half-life of IgG is ~25 days).[83,84] In this setting, it is logical to only apply invasive MRD testing when monoclonal immunoglobulins have become undetectable, which was the basis for current IMWG response criteria.[71] This strategy of MRD assessment has been challenged by novel highly effective therapies (e.g., CAR-T cells and four-drug combinations) capable of eradicating all measurable tumor cells from the bone marrow long before monoclonal proteins have cleared from the serum.[85,98] Most of these patients go on to achieve a conventional CR up to several months later, indicating that early MRD negativity in the bone marrow is an early predictor of deep and durable responses irrespective of the serum protein levels at the time of assessment.

The most commonly used laboratory techniques to assess MRD status in the bone marrow are (1) flow cytometry for the aberrant cell-surface phenotype of myeloma cells and (2) NGS[86] for tracking of tumor-specific immunoglobulin V(D)J rearrangement sequences.[87,88] There is currently no evidence that one methodology is superior to the other, but clinical trials which include head-to-head comparison of both approaches are ongoing. There are however important practical considerations for choosing an assay. Flow cytometry is more widely accessible, but there is great variability in assay performance between centers; interpretation relies on local expertise; and fresh bone marrow aspirates are required for analysis. By contrast, highly standardized NGS assays are offered commercially and can be performed using stored samples but require a pre-treatment sample with high degree of tumor infiltration which is required to identify tumor-specific immunoglobulin sequences for tracking. Importantly, flow cytometry assays require 3 to 10 million bone marrow cells to reach 10^{-6} sensitivity, while NGS assays generally require only 3 million cells. Both assays are highly dependent on sample quality and initial bone marrow aspirate pulls are recommended for use in order to avoid false negatives due to hemodilution.

In keeping with the view of MRD negativity as a surrogate marker for cure, there is a constant drive to develop more sensitive MRD testing strategies. As mentioned above, there are practical limitations to the sensitivity of bone marrow MRD testing. Moreover, a single bone marrow aspirate represents a random sampling of cells from a single site from a patient with MM which is a patchy disease. Current research efforts are directed to develop non-invasive methodologies that may complement bone marrow-based MRD testing. These include highly sensitive mass spectrometry assays for monoclonal proteins in serum, circulating tumor cells, circulating tumor DNA, and novel imaging modalities. First-in-human studies have shown highly promising results from targeted PET-CT, using radiolabeled monoclonal antibody (anti-CD38) to increase sensitivity and specificity over conventional FDG-based PET-CT.[89,90]

Staging, Prognosis, and Risk Stratification

MM is a heterogeneous disease with a varied outcome, with 20% of patients having a survival of less than 2 years, whereas over 40% of patients have more than a 10–year survival. Therefore, it is critically important to identify disease features that allow one to identify low versus high-risk disease to counsel the patient, and in some cases to better plan and sequence therapeutic interventions. Moreover, accurate risk stratification defines precise patient populations by which clinical trial results can be appropriately evaluated. Given these considerations and needs, various prognostic variables have been identified,[91] including measurement of disease burden related factors (such as β_2-microglobulin, LDH, number or nature of lytic bone lesions, hypercalcemia), tumor biology–related factors (such as genomic changes,[92] plasma cell labeling index[93]), tumor microenvironment–related factors, patient-related factors, such as age, renal failure, albumin, and performance status, and treatment-related factors, such as achieving a CR, or MRD negative status.

The history of risk stratification (i.e., staging) and prognostication for MM began with systems which assessed the extent of end-organ damage, then moved to systems which predominantly assessed disease burden. However, in an era of improved understanding of underlying disease pathogenesis and improving novel therapies which may be relatively agnostic to (high) disease burden, MRD detection is increasingly moving to systems which attempt to capture disease biology in its many facets. Of note, among cancers the staging of MM and related disorders is relatively unique in being entirely unrelated to anatomic considerations, in distinction to staging systems for solid tumors and indeed even for most lymphomas.

TABLE 91.6 **Standard Risk Factors for Multiple Myeloma and the Revised International Staging System**

Prognostic Factor	Criteria
International Staging System (ISS) Stage	
• I	Serum β_2-microglobulin <3.5 mg/L, serum albumin ≥ 3.5 g/dL
• II	Not ISS stage I or III
• III	Serum β_2-microglobulin ≥ 5.5 mg/L
Chromosomal Abnormalities (CA) by Interphase Fluorescence in Situ Hybridization	
• High risk	Presence of del(17p) and/or translocation t(4;14) and/or translocation t(14;16)
• Standard risk	No high-risk CA
LDH	
• Normal	Serum LDH below the upper limit of normal
• High	Serum LDH above the upper limit of normal
A New Model for Risk Stratification for Multiple Myeloma Revised International Staging System Stage	
• I	ISS stage I and standard-risk CA by iFISH and normal LDH
• II	Not R-ISS stage I or III
• III	ISS stage III and either high-risk CA by iFISH or high LDH

CA, Chromosomal abnormalities; *iFISH*, interphase fluorescence in situ hybridization; *ISS*, International Staging System; *LDH*, lactate dehydrogenase; *MM*, multiple myeloma; *R-ISS*, revised International Staging System.
From Greipp PR, San Miguel J, Durie BG, et al. International staging system for multiple myeloma. *J Clin Oncol.* 2005;23(15):3412.

The Durie-Salmon staging system[94] was published in 1975 on the basis of only 71 patients that were assessed for severity of anemia, presence of hypercalcemia, number/level of skeletal lesions, the size of the M-protein in blood and urine, and presence or absence of renal injury. The subsequent ISS was published in 2005 and was a simple system which assessed the overall patient by means of serum albumin levels, and also crudely measured disease burden as defined by serum β_2-microglobulin levels.[95] With the advent of novel therapies, the discriminating power of the ISS had decreased over time, and currently the most commonly used system for clinical trials and most practitioners is the R-ISS (Table 91.6, Fig. 91.11),[96] which adds to the ISS by beginning to account for the biology of MM. The LDH is a crude measure of the proliferation rate and turnover of malignant cells, and the R-ISS also adds a handful of the more highly validated cytogenetic/FISH changes which reflect the biology of each patient's MM in order to make staging more accurate. R-ISS staging is able to predict both event-free survival (EFS) and OS and is valid regardless of age, geographic region, study site, use of standard-dose therapy or high-dose melphalan (HDM), and use of novel agents. Also of note, although presumably such tests reflect disease biology as described above in the Pathogenesis section, GEP-based scoring systems have also been described by a number of groups. Although useful, these remain investigational and have not entered routine clinical practice.

In addition, newer genomic correlates of outcome have been validated in a number of studies and are considered standard predictive markers. Continuing efforts are focused on further refining risk stratification, with improved understanding of MM pathogenesis and genomic changes translating to meaningful risk stratification tools. For example, emerging data suggest that biallelic *TP53* gene loss[92] or more than three copies of chromosome 1q are associated with poor outcomes,[97] and investigators have combined recurrent molecular adverse features with the ISS and proposed an ISS mutation score to identify high-risk patients.[92]

Finally, it has become increasingly evident that disease sensitivity to therapy, which likely reflects the underlying biology of a given patient's neoplastic PCs, is critical for predicting a patient's prognosis. As discussed in the Minimal Residual Disease section, achievement of very low disease levels (MRD negativity) at the conclusion of therapy is predictive of improved outcomes such as PFS and likely even OS. Although chronic myeloid leukemia (CML) management currently leads the way with respect to the evidence relating the speed

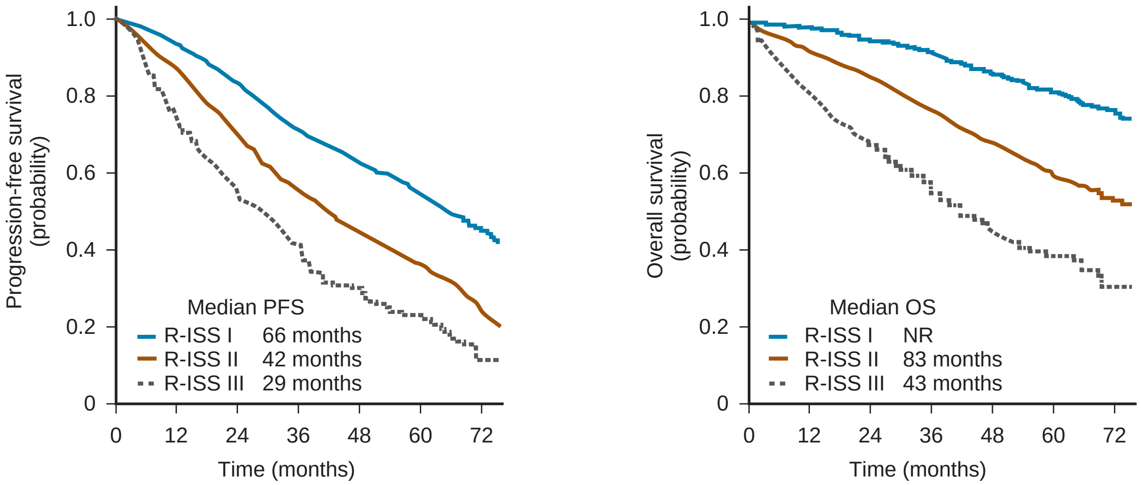

Figure 91.11 Revised International Staging System *(R-ISS)* is able to predict both event-free survival *(left panel)* and overall survival *(OS; right panel)*. *NR*, Not reached; *PFS*, progression-free survival.

and depth of response achieved following treatment to patient outcomes, a number of other hematologic neoplasms, including acute lymphoblastic leukemia (ALL), acute promyelocytic leukemia (APL), and even other types of AML and chronic lymphocytic leukemia (CLL) are also moving in this direction. We speculate that MM therapy and monitoring may follow an analogous path, with both the speed and depth of response being shown to be prognostically important for building the risk profile of a given patient's disease. Indeed, the ADVANCE trial as well as other future clinical trials in MM are incorporating MRD-directed endpoints.

GENOMIC BIOMARKERS

Genomic alterations identified in MM cells before treatment can improve prognostic risk stratification over the use of clinical features alone. Historically, cytogenetic analysis and fluorescence in-situ hybridization to identify *IGH* translocations and large chromosomal aneuploidies have been the standard approach. This was supplemented in some centers with array-based methods capable of identifying genome-wide copy number changes with high accuracy. Recently, NGS has emerged as a new standard of care technology capable of identifying relevant genomic alterations with a single assay. Today, the most relevant technological platforms for routine clinical use are targeted hybridization-capture sequencing panels and low-coverage WGS. Both of these strategies can replace older methods like FISH, while providing additional information about SNVs, small insertions/deletions, SVs, and CNAs, depending on the specific method used.

Currently the main genomic biomarkers used to predict adverse prognosis are the following: *IGH* translocations involving *MMSET* (t4;14), *MAF* (t14;16), or *MAFB* (t14;20); bi-allelic inactivation of *TP53* (i.e., deletion and mutation); and gain of chromosome 1q21 (three or more copies). Genomic information has been incorporated in the revised R-ISS prognostic score, which is simple and commonly used. There is however a great need for prognostic scores which incorporate the wide array of genomic alterations that can now be identified using increasingly accessible NGS assays.

Transcriptome-based biomarkers are appealing because they have the potential to assess the functional state of the tumor. Several prognostic risk scoring systems based on GEP have been proposed, but none have been widely adopted.[21–23] This is partially due to challenges with reproducibility, but also the greater availability of cytogenetic analyses. More recently, RNA sequencing-based models have been developed to predict patient benefit from different therapies including IMIDs, Pis, and ASCT.[98,99] The role of RNA-based biomarkers in the routine care of patients with MM remains to be determined.

DIFFERENTIAL DIAGNOSIS

The diagnosis of MM does not often present a dilemma and is based largely on laboratory and imaging investigations together with the clinical presentation. However, no single symptom or group of symptoms is pathognomonic, including even the highly suggestive triad of anemia, hypercalcemia, and lytic lesions. For example, though less prevalent than MM, adult T-cell leukemia/lymphoma (ATLL), a mature T-cell neoplasm, can present with a similar clinical picture (see Chapter 89),[100] as can certain aggressive mast cell neoplasms (see Chapter 75).[101,102] However, tissue biopsy easily resolves any confusion, as differentiating T- or mast-cell neoplasms versus plasma cells is usually pathologically straightforward. On the other hand, pathologic entities related to MM which can share certain (mmune)histologic features include plasmablastic lymphoma[103,104] and lymphoplasmacytic lymphoma.[105] Fortunately, these entities can generally be clinically distinguished from MM, for example with a history of HIV infection or splenomegaly, respectively.

With respect to the diagnosis of MM, a significant number of patients present with minimal symptoms, delaying diagnosis. Most frequently, in a relatively asymptomatic patient, investigations are carried out because of increased total protein levels, proteinuria, renal dysfunction, and/or bone pain. An older patient with any of these features or unexplained back pain, anemia, or recurrent infections should be evaluated for MM. In general, a diagnostic workup is pursued in two steps: first, the demonstration of a monoclonal protein and monoclonal plasma cells, and second, identification of end-organ damage or biomarker criteria that define MM. This is essential to differentiate early-stage plasma cell disorders such as MGUS or SMM (see Chapter 90) from active symptomatic MM (see Table 91.3). Once a diagnosis of MM is suspected, investigations should be carried out as detailed in the box on Investigations for Patients Suspected or Confirmed to Have Newly Diagnosed Multiple Myeloma. Detection of a monoclonal protein requires the performance of a protein electrophoresis and immunofixation as well as a 24-hour urine collection and serum-free light chain measurements. Both serum protein electrophoresis and quantitative immunoglobulins are required, and an immunofixation is important to identify the type of paraprotein present. The bone marrow is examined for the detection of clonal plasma cells, mainly by histology but also importantly by immunostaining or flow cytometry using κ/λ staining and by demonstrating aberrant cell surface molecules (see Table 91.2). Determination and quantitation of clonal marrow plasma cell numbers are required to differentiate SMM from MGUS, from active myeloma; patients with greater than 10% and less than 60% marrow plasma cells are considered to have SMM, with MGUS and active myeloma respectively bookending plasma cell burdens below and above this range. Detailed investigations searching for evidence of organ damage should be undertaken to look for bony lesions, renal dysfunction, anemia, and hypercalcemia. It should again be reiterated that in addition to bloodwork, bone marrow aspirate and biopsy to establish a clonal neoplastic PC disorder, as well as cross-sectional imaging with total body MRI (without contrast) and/or PET/CT are mandatory for the initial diagnostic evaluation of myeloma. Detailed diagnostic criteria are summarized in Table 91.3.

INDICATIONS FOR TREATMENT

Therapy for MM is warranted when an organ function is compromised or will become imminently compromised, and this forms the crux of the IMWG 2014 diagnostic criteria for MM. To that end, the acronym *CRAB* (hypercalcemia, renal impairment, anemia, and bone disease) defines the major manifestations of end-organ damage. Additionally, symptomatic hyperviscosity, amyloidosis, monoclonal immunoglobulin deposition disease, recurrent bacterial infections, and progressive peripheral neuropathy attributed to a plasma cell disorder can also be indications for treatment. Additionally, the IMWG has defined the following events, which strongly predict early progression to end-organ damage, thereby warranting systemic therapy: (1) clonal bone marrow plasma cell percentage (aspirate, biopsy, or flow cytometry whichever is higher) of 60% or above, (2) elevated serum free light chain ratio (involved/uninvolved) of 100 or higher, with the associated light chain at least 100 mg/L, and (3) more than one characteristic focal lesion, in the bone or bone marrow, visualized by MRI.[106] We emphasize that MRI lesions may be bone *marrow*-based and not lytic lesions per se. Of course, one or more osteolytic lesions using essentially any imaging modality also represents symptomatic bone disease and justifies the initiation of therapy. Of note however, the presence of clonal plasma cells coupled *solely* with isolated osteoporosis, in the absence of meeting other criteria for MM defining events, do not secure the diagnosis of MM, and cannot be used to justify beginning treatment.

Response Criteria

The most recent IMWG response criteria[71] from 2016 define both "standard" criteria as well as MRD-based criteria. In brief, serial monitoring and comparison of the size of the M-protein in blood and/or urine, free light chains, and size of plasmacytomas allows for numeric calculations from a reference value, typically the most recent peak value. Although the actual criteria are highly detailed to account for unusual entities such as pure free light chain myeloma and true nonsecretary myelomas, we highlight below the most commonly used aspects of these criteria, reflecting increasing depths of response.

A "minimal response" (MR) is defined as 25% to 49% decrease in size of the serum M-spike, and a 50% to 89% reduction in urine M-spike if measured. Additionally, the size of any measurable (soft tissue) plasmacytomas should have decreased by at least 50%. A "partial response" (PR) is defined as 50 to 89% decrease in size of the serum M-spike, and a 90% or greater response in urine M-spike. If only free light chains are present, a 50% reduction in the difference between involved vs. uninvolved light chains is required. A "very good partial response" (VGPR) is defined as greater than 90% decrease in serum and urine M-spike, with urine M-protein <100 mg/day. A "complete response" (CR) is defined by absence of an M-spike in the serum and urine, negative immunofixation studies, total radiographic resolution of any previously identified plasmacytomas, and <5% plasma cells in bone marrow sampling. A "stringent complete response" (sCR) adds the absence of marrow PC clonality by immunohistochemistry as well as a normal free light chain ratio to the criteria for the achievement of CR.

On the other hand, "progressive disease" (PD) would be defined by a 25% increase (from the nadir) of the serum M-spike (absolute increase >0.5 g/dL), urine M-spike (absolute increase > 200 mg/day), a 25% increase in the difference between involved and uninvolved free light chains (absolute increase >10 mg/dL), growth of new anatomic lesions, or >50% increase in the size of an existing lesion or plasmacytoma. "Stable disease" (SD) in an MM patient is defined as a clinical condition which fulfills none of the above criteria for PD, MR, PR, VGPR, CR, or sCR.

Lastly, the MRD-based response criteria presuppose levels of response at least equivalent to sCR including absence of clonal PCs by immunohistochemistry, and then further assesses for clonal plasma cells by flow cytometry, NGS, or other approaches to declare MRD positivity or negativity. As discussed above in the Minimal Residual Disease section, the details of MRD response criteria including the ideal cutoff (10^{-5} or 10^{-6}), as well as related considerations for the significance of MRD positivity vs. negativity remain areas of active investigation.

Solitary Plasmacytoma: Medullary and Extramedullary

Solitary plasmacytomas are rather uncommon and account for 6% of plasma cell neoplasms. The incidence is 0.3 per 100,000 person-years in the United States. A diagnosis of a solitary plasmacytoma requires meeting all of the following criteria:[106] histologic confirmation of clonal plasma cells at a single anatomic site; a negative bone marrow with absence of clonal plasmacytosis; no distant bone involvement; and no anemia, hypercalcemia, or renal impairment (see Table 91.3). In particular, note that presence of two plasmacytomas, or more than 10% (clonal) bone marrow PCs in association with a single plasmacytoma meet the diagnostic criteria for MM. Solitary plasmacytomas may present as a single bony lesion (medullary) or as a soft tissue lesion outside the bone (extramedullary), with solitary plasmacytomas involving the bone being more common.

Patients presenting with solitary plasmacytomas require a complete workup to confirm the diagnosis and to thoroughly exclude MM, as management differs drastically for patients with a solitary plasmacytoma (locoregional therapy) vs. MM (systemic therapy). Given this, patients should undergo serum protein electrophoresis, serum immunofixation, serum free light chain assay, UPEP, urine immunofixation, a diagnostic bone marrow aspiration and biopsy with sensitive flow cytometry analysis to detect clonal plasma cells, and detailed skeletal imaging that should include PET/CT and/or total body MRI. In our opinion, because of insufficient sensitivity, a negative plain film skeletal series alone is not sufficient to rule out MM in resource-abundant practice settings.

Presumably because of the burden of plasma cells, one-third of patients with solitary plasmacytoma may present with a detectable monoclonal paraprotein in the serum, urine, or both. However, persistence of the monoclonal paraprotein after definitive locoregional therapy is predictive of recurrence, as it reflects the presence of viable neoplastic PCs which continue to secrete the paraprotein. Of note, patients with clonal but less than 10% plasma cells in a bone marrow biopsy specimen[107] (termed "solitary plasmacytoma with minimal marrow involvement") may be managed with locoregional therapies directed against the solitary lesion initially. However, these patients by definition have clonal neoplastic cells outside the field of treatment, and have a higher risk of progression than those without any marrow involvement. Indeed many of these patients do progress to MM over subsequent years of follow-up.

Solitary plasmacytomas are generally treated with local radiation therapy, although some solitary plasmacytomas of the bone may require surgical intervention for stabilization followed by local radiation therapy. Depending upon their location, small extramedullary soft tissue plasmacytomas may be treated with excisional biopsy alone. Because of the risk of recurrence or progression to MM, after definitive locoregional therapy, at a minimum yearly imaging studies for at least 5 years is recommended. Serial appropriate blood work and urine studies including studies for paraproteins (generally every 3 to 6 months) are warranted. The disease-free survival at 10 years is approximately 50% for patients with solitary plasmacytomas. For those patients who are not cured, progression to MM generally occurs within 5 years from initial diagnosis. Patients presenting with medullary plasmacytomas, with persistence of a monoclonal paraprotein after treatment for the solitary plasmacytoma, those with detectable low levels of clonal plasma cells in the bone marrow, patients between 40 and 60 years of age, and patients of African American descent are at higher risk for progression to MM. Such patients should be considered for potentially even closer surveillance for disease progression.

Plasma Cell Leukemia

PCL[108] is a rare and highly aggressive malignant plasma cell disorder, currently defined by the IMWG as greater than 0.5 to 2×10^9 circulating plasma cells per liter, or greater than 5% to 20% of nucleated cells being PCs in the peripheral blood.[109] The precise numeric threshold to be used to establish the diagnosis varies by investigator and has not been prospectively validated, but most agree that satisfying one of the two criteria mentioned above are sufficient.[110] Signs and symptoms are similar to those of classical MM, although primary PCL patients are generally younger than their MM counterparts, manifest high disease burdens, have hepatosplenomegaly, and more frequently display other extramedullary signs and symptoms than patients with MM.

There are no pathognomonic gene mutations or cytogenetic abnormalities of PCL, yet the t(11;14) translocation is common in this disease entity, with up to half of patients having this abnormality, as compared to 15% to 20% of MM patients. Why this translocation, which is generally viewed as standard-risk or even favorable in MM, is present more often in PCL patients is unclear. Since the BCL-2 inhibitor venetoclax has shown efficacy in t(11;14) MM and in mantle cell lymphoma, there is significant interest presently in studying its use in PCL.

Most primary PCL patients present with a high tumor burden[109] corresponding to R-ISS 3, and this entity should be managed in a similar fashion as extremely high-risk newly diagnosed MM patients as described in detail below; urgent and aggressive combination therapy is warranted, employing the most potent regimens appropriate for a given patient. For transplant-eligible patients, high-dose therapy is generally warranted. All patients, regardless of transplant eligibility, should receive maintenance therapy, as relapses are unfortunately common with PCL. Secondary PCL is a rare complication of treated MM and occurs in under 5% of patients. Its incidence may be increasing as the OS of MM patient's increases. It is generally a late manifestation of multiply relapsed/refractory MM and treated as such. It often carries a poor prognosis.

Overview of Therapy for Multiple Myeloma

Patients with diagnosis of MM should be treated with systemic medical therapy. To warrant the diagnosis of MM, patients generally present with symptoms caused by the myeloma tumor mass, such as anemia, lytic bone disease, hypercalcemia, or renal impairment (the "CRAB" criteria). Other MM-defining events that warrant systemic therapy include a clonal bone marrow plasma cell percentage as a percentage of nucleated cells (on aspirate, biopsy, or flow cytometry, whichever is higher) of 60% or above, elevated serum free light chain levels of at least 100 mg/L associated with an involved/uninvolved free light chain ratio of 100 or higher, and/or more than one focal lesion, each at least 5 mm in diameter on MRI. The presence of any one of these three "biomarker criteria" portend a high risk of early progression to frank end-organ damage as defined by the CRAB criteria and therefore such patients are also classified as having active MM. In addition, patients with a low tumor burden per se but with organ dysfunction caused by a paraprotein or immunodeficiency such as monoclonal immunoglobulin deposition disease or AL amyloidosis of an organ, progressive peripheral neuropathy or recurrent serious infections may also require systemic therapy (see box on Rare Disorders Associated With Monoclonal Proteins and/or Plasma Cells).[111]

Front-line therapy for MM as well as entry onto clinical trials has traditionally been determined by whether the patient is sufficiently medically robust to be able to proceed with HDM chemotherapy followed by ASCT, the so called "transplant eligibility." This longstanding paradigm, however, may be changing in the era of increasingly potent upfront therapies and the gradual adoption of MRD testing and MRD-driven decision-making.[112] Transplant eligibility in MM[113,114] is largely a clinical decision based on organ function, comorbidities, patient age, and social support, although formal scoring systems exist (see Chapter 157). The treatment given before HDM chemotherapy and ASCT, if performed, is termed induction therapy. The term consolidation can be confusing: it traditionally referred to HDM and ASCT itself, although various investigators also use the term consolidation to refer to additional cycles of combination therapy after HDM, or induction therapy in transplant ineligible patients. Regardless of whether patients undergo consolidation or high-dose chemotherapy, in the United States all patients treated by expert myeloma clinicians receive subsequent, generally lower-intensity maintenance therapy until progression, with the goal of deepening treatment responses, prolonging time to the next active treatment, and improving OS.

TREATMENT OF NEWLY DIAGNOSED MYELOMA

During the past two decades, tremendous advances have been made in the treatment of MM patients, with concomitant dramatic improvements in OS,[115] driven largely by the availability of the so-called novel agents belonging to a number of drug classes (Fig. 91.12). Therapeutic advances have resulted in an overall response rate (ORR) of essentially 100% and increasingly high rates of CR and MRD negativity. Modern advances in induction regimens are focused on increasing the CR rate and MRD negative rate. These modern regimens have largely supplanted older regimens centered around traditional cytotoxic chemotherapeutic agents. Although not all the drugs mentioned below are FDA-approved or United States National Comprehensive Cancer Center (NCCN) compendium-listed for induction therapy per se, the commonly used modern induction agents include (1) the IMiDs thalidomide, lenalidomide, and pomalidomide; (2) the PIs bortezomib, ixazomib, and carfilzomib; (3) the anti-SLAMF7 monoclonal antibody elotuzumab; and (4) the anti-CD38 monoclonal antibodies daratumumab and isatuximab. These drug classes, together with steroids, traditionally either dexamethasone or prednisone (MP), are generally combined, in some cases with the addition of older alkylating drugs, to form the backbone of most modern induction regimens. Such regimens typically include three, four, or even more drugs in combination (see box on Treatment of Newly Diagnosed Multiple Myeloma).

Improvements in regimens with non-overlapping mechanisms of action, and non-overlapping toxicities, as reviewed below, have now advanced to the point where the most modern of therapies[116] achieve an ORR of essentially 100%, and even a VGPR rate of nearly 100%, with high rates of MRD negativity at the end of induction therapy.[117] Because of these successes, the rapid achievement of deep responses, and achieving CRs and MRD-negative status is becoming

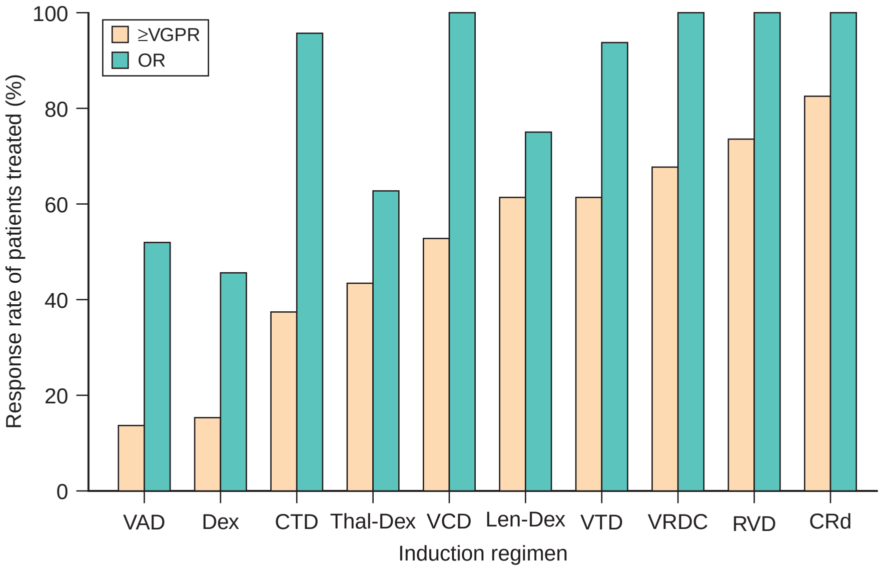

Figure 91.12 RESPONSE RATES IN NEWLY DIAGNOSED MYELOMA PATIENTS WITH COMMONLY USED INDUCTION REGIMENS. *CRd*, Carfilzomib, lenalidomide and dexamethasone; *CTD*, cyclophosphamide, thalidomide and dexamethasone; *Dex*, dexamethasone; *Len–Dex*, lenalidomide and dexamethasone; *MM*, multiple myeloma; *OR*, overall response; *RVD*, revlimid, bortezomib and dexamethasone; *Thal–Dex*, thalidomide and dexamethasone; *VAD*, vincristine, doxorubicin and dexamethasone; *VCD*, bortezomib, cyclophosphamide and dexamethasone; *VGPR*, very good partial response; *VRDC*, bortezomib, lenalidomide, dexamethasone and cyclophosphamide; *VTD*, bortezomib, thalidomide and dexamethasone.

TREATMENT OF NEWLY DIAGNOSED MULTIPLE MYELOMA

- Confirm patient has symptomatic myeloma by CRAB criteria, or greater than 60% marrow plasma cells, or serum involved/uninvolved free light chain ratio greater than 100 with the involved free light chain greater than 10 mg/dL, or two or more lesions, each at least 5 mm in diameter, on total body magnetic resonance imaging (MRI). Patients with monoclonal gammopathy of unknown significance or smoldering multiple myeloma should not be treated outside a clinical trial.
- Risk stratify and assess disease burden using the Revised International Staging System, quantitative studies of paraproteinemia, lactate dehydrogenase and β_2 microglobulin, bone marrow plasma cell burden, genomic profiling, and flow cytometric features. These are helpful for prognostication and to develop a long-term treatment plan. Although initial treatment is generally not affected by risk category per se, consideration of more aggressive consolidation approaches in eligible patients could be warranted.
- Induction: most transplant-eligible and transplant-ineligible patients can be treated with a three or four-drug regimen, typically composed of a steroid (prednisone or dexamethasone), an immunomodulatory drug, and a proteasome inhibitor, with addition or substitution of an alkylating agent (cyclophosphamide, melphalan) and/or monoclonal antibody.
- Selection of therapy should be influenced by patient characteristics.
- Renal dysfunction: safe agents include daratumumab, bortezomib, carfilzomib, cyclophosphamide, thalidomide, and steroids.
- Neuropathy: agents that can be considered are daratumumab, lenalidomide, carfilzomib cyclophosphamide, and steroids.
- Elderly or frail patients: consider dose or schedule attenuation or use of fewer agents. Daratumumab-based regimens are well-tolerated in general.
- Convenience: use of an all-oral versus intravenous agent regimen.
- Assess treatment responses after each cycle of induction therapy and treat to best response (generally up to 8 cycles with modern therapies). For transplant-eligible patients, stem cell collection is generally performed no later than cycle 6 of induction due to cumulative stem cell toxicity from both novel agents and conventional cytotoxic drugs. For patients who achieve serologic very good partial response (VGPR) or better and have no clinical evidence of disease at the end of induction, assess minimal residual disease status (typically by repeat bone marrow biopsy).
- Patients not achieving VGPR, or minimal residual disease (MRD) positive patients, can undergo additional cycles of induction therapy to achieve MRD negativity. Eligible patients whose best response to treatment is still with disease present should be considered for a single autologous transplant with high-dose melphalan. A second autologous transplant (so-called “tandem transplant”) or autologous transplant followed by allogeneic transplant (“auto-allo”) should not be performed outside the confines of a clinical trial.
- Maintenance: following transplant or optimal induction therapy (to best response), all patients should receive maintenance therapy, most commonly with an oral immunomodulatory agent and less commonly with proteasome inhibitor, or anti-CD38 antibody. For high-risk patients or suboptimal responders including those not achieving MRD negativity after high-dose melphalan and autologous transplant, combination maintenance therapy can be considered. Maintenance delays disease progression and time to next treatment and can further improve the depth of response.
- Achieving an MRD negative status is associated with excellent patient outcomes. Conversion to MRD negativity can occur in the setting of induction, autologous transplant, or maintenance.

a benchmark for the evaluation of further improvements in therapy. As described above, MRD negative status predicts a better PFS and is associated with improved patient outcomes.

In general, treatment should be tailored to both patient characteristics (comorbidities such as pre-existing diabetes or hyperglycemia, organ dysfunction, performance status, venous thromboembolism risk, preferences with respect to toxicity) and disease characteristics, primarily with respect to the clinician’s assessment of a particular malignancy’s biologic aggressiveness, as reflected by disease presentation, genomic abnormalities, cell surface markers, and disease burden (as measured by paraprotein levels, number and size of lesions on imaging, bone marrow PC percentage, etc.). For the practicing clinician, these considerations are further influenced by region-specific access to medications, healthcare and insurance coverage of drugs, patient logistical considerations (e.g., the ability to make frequent clinic visits for subcutaneous injections or IV infusions), and patient preferences with respect to specific toxicities, such as neuropathy.

Chemotherapy with Cytotoxic Agents

In the United States and a number of other countries, combinations of novel agents, including the IMiDs, PIs, and oftentimes monoclonal antibodies now form the standard-of-care backbone for the induction therapy of MM patients. However, because of challenges due to cost and access to novel agents in some regions as well as unique toxicities which may occur with some novel agents, traditional cytotoxic agents still play a role in the treatment of patients with both newly diagnosed and relapsed disease, as well as during high-dose therapy during consolidation.

Alkylating agents, primarily cyclophosphamide and melphalan, have been most frequently used as cytotoxic therapy for MM. This has been followed by the anthracyclines (primarily doxorubicin) and a handful of other cytotoxic drugs such as platinum chemotherapy, the vinca alkaloids, and topoisomerase II inhibitors. The majority of these other classes of agents are used in modern practice only as part of a multi-day infusional combination cytotoxic chemotherapy regimens and are given primarily in the salvage setting.

Melphalan and cyclophosphamide were introduced in the management of MM in the early 1960s. To this day, they continue to play a pivotal role in treatment of MM. Melphalan + MP and cyclophosphamide + dexamethasone (CyD) are flexible and well-tolerated regimens which can be given orally or intravenously, and remain useful both in low resource environments, and to treat patients too frail for, or with contraindications to novel agents or biologics. Melphalan remains the agent of choice for high-dose therapy with stem cell rescue, and both melphalan and cyclophosphamide also continue to be used in combination with novel agents and other cytotoxic drugs, both during induction and the management of relapsed disease (summarized in Table 91.7).

Although primarily historical of interest, clinicians seeing heavily pretreated patients may continue to encounter patients with longstanding MM who were previously treated with VAD (vincristine, Adriamycin [doxorubicin], and dexamethasone), a common regimen used widely prior to the widespread adoption of novel agents. In some less frequently used regimens, the anthracycline doxorubicin or liposomal doxorubicin are also combined with novel agents. Finally, infusional chemotherapy using combinations of cytotoxic agents in the form of PACE or DCEP, with or without additional novel agents, has also been used previously in the newly diagnosed setting, most prominently by investigators at the University of Arkansas in a series of high-intensity regimens centered around cytotoxic chemotherapy under the rubric of “Total Therapy.”[118–120] In modern practice, such regimens are largely reserved for relapsed patients due to their dramatically higher toxicity and requirement for hospitalization for several days to administer these therapies as well as the intensive subsequent outpatient follow-up necessary to monitor for and ameliorate resulting toxicities. As an ancillary note, although studies in lymphoma have successfully replaced cisplatin with carboplatin or oxaliplatin in many (salvage) regimens to reduce nephrotoxicity, we are not aware of similar data in myeloma. When a platinum drug is required, cisplatin appropriately dosed for renal function remains the standard of care. Additionally, in some infusional cytotoxic chemotherapy regimens, it may be possible to replace standard doxorubicin with its liposomal formulation (Doxil) in order to minimize the risk of cardiotoxicity.

TABLE 91.7 Selected Regimens Utilizing Cytotoxic Agents

Regimen Abbreviation	Agents
MP	Melphalan, prednisone
CyD	Cyclophosphamide, dexamethasone
CTD	Cyclophosphamide, thalidomide, dexamethasone
CyPR	Cyclophosphamide, prednisone, Revlimid (lenalidomide)
CYKLONE	Cyclophosphamide, Kyprolis (carfilzomib), thalidomide, dexamethasone
KRDC	Kyprolis (carfilzomib), Revlimid (lenalidomide), dexamethasone, cyclophosphamide
MPR	Melphalan, prednisone, Revlimid (lenalidomide)
MPT	Melphalan, prednisone, thalidomide
RVDC	Revlimid (lenalidomide), Velcade (bortezomib), dexamethasone, cyclophosphamide
VAD	Vincristine, Adriamycin (doxorubicin), dexamethasone
CVAD	Cyclophosphamide, vincristine, Adriamycin (doxorubicin), dexamethasone
TAD	Thalidomide, Adriamycin (doxorubicin), dexamethasone
TVAD	Thalidomide, vincristine, Adriamycin (doxorubicin), dexamethasone
CyBorD	Cyclophosphamide, bortezomib, dexamethasone
VMP	Velcade (bortezomib), melphalan, prednisone
VMPT	Velcade (bortezomib), melphalan, prednisone, thalidomide
PACE	Platinol (cisplatin), Adriamycin (doxorubicin), cyclophosphamide, etoposide
DCEP	Dexamethasone, cyclophosphamide, etoposide, cisplatin
BBD	Bendamustine, bortezomib, dexamethasone

Combinations of Three, Four, or More Classes of Novel Agents

It has long been established that it is possible to combine drugs with different mechanisms of action with non-overlapping toxicities without compromising the ability to deliver an effective dose in order to maximize anti-myeloma effects, eliminate potentially resistant clones, deepen the depth of response, and prolong remission duration. Optimizing the precise combination drug, schedules, and dosing of a steroid, IMiD, PI, monoclonal antibody, and in some cases alkylating agent for each population of newly diagnosed MM patient continues to be a challenge. Since the toxicities and route of drug elimination characteristic of commonly used agents differ sometimes even within the same drug class, it is useful to consider patients as belonging to several distinct subpopulations with respect to the feasible drugs that can be administered to each group.

- *Renal failure:* Since such patients are ineligible for lenalidomide or pomalidomide therapy, regimens containing alkylating agents, thalidomide, PIs, and monoclonal antibodies are reasonable options. This includes several combination therapies: CyBorD, IRd, VTD, daratumumab-VTD, carfilzomib, cyclophosphamide, dexamethasone (KCyD), and the CYKLONE regimen. The regimen of daratumumab + Cyclophosphamide, bortezomib, and dexamethasone (CyBorD) is now NCCN compendium-listed and is also a suitable choice. Older regimens such as MP or cyclophosphamide + dexamethasone may also be appropriate if there is difficulty in gaining access to novel agents.
- *Severe heart failure with reduced ejection fraction, concomitant amyloid cardiomyopathy, or related entities:* Such patients should likely avoid carfilzomib-based induction regimens, instead receiving regimens with bortezomib as the PI (e.g., RVd, daratumumab/lenalidomide/dex, daratumumab-VTD). Daratumumab can be used in this patient population as long as the fluid status of the patient is carefully monitored. Liposomal doxorubicin-based combination therapy may be considered in special circumstances.
- *Pre-existing neuropathy or high concerns for neuropathy:* In this situation one should avoid bortezomib and thalidomide. By contrast the next-generation PI carfilzomib carries essentially no neuropathy risk. If bortezomib is used, a subcutaneous administration is favored over intravenous[121] in order to decrease neurotoxicity. Given this, regimens such as KRd and DRd are associated with less neuropathy. Clinical trial regimens are being evaluated which add daratumumab to an appropriate triplet of IMiD + PI + steroid.
- *Otherwise frail and/or transplant-ineligible, but without severe cardiac or renal disease:* consider DRd, RVd-lite, or Rd
- *Medically fit, and without significant organ dysfunction:* KRd is an NCCN compendium-listed regimen in the United States and covered by most insurers, yielding excellent responses for patients who can tolerate this regimen. Although initially studied with carfilzomib as twice-weekly infusions on back-to-back days, in modern schedules once-weekly carfilzomib is equally acceptable. In rare instances with very aggressive and symptomatic disease in otherwise fit and younger patients, combinations of infusional chemotherapy with novel agents such as VTD-PACE or KRd-PACE can be considered. Again, clinical trials adding daratumumab to an IMiD/PI/steroid backbone are attractive both for advancing the field and expected patient outcomes.

Selected Trials of Induction Therapy With Novel Agents

Although the large number of high-quality trials using these agents are impossible to summarize comprehensively, below are highlighted a number of seminal studies which have moved the MM treatment field forward. The phase 3 SWOG 0777[122] trial compared the doublet of lenalidomide and dexamethasone versus the triplet of lenalidomide, bortezomib, and dexamethasone (RVd) in transplant-eligible patients, and demonstrated superior PFS and OS with acceptable toxicities with a PI and IMiD containing triplet over doublet. Next, the EVOLUTION trial compared RVd vs. a triplet of bortezomib, cyclophosphamide, and dexamethasone (CyBorD or VCd) or all four agents together (VCRd). Deeper responses were reported in regimens which contained lenalidomide vs. those that did not, with RVd and VCRd performing the best, demonstrating again the importance of IMiDs as a component of induction therapy. Finally, a study by Moreau and colleagues comparing subcutaneous vs. intravenous bortezomib administration, albeit in relapsed/refractory disease, demonstrated equal efficacy but markedly less neuropathy with subcutaneous bortezomib.[121] This route of administration is standard of care in essentially all settings where bortezomib is given. Also of note, the oral proteasome inhibitor ixazomib has similar pharmacologic properties as bortezomib. Ixazomib together with lenalidomide and dexamethasone (IRd[123,124]) is a regimen with pharmacologic properties highly similar to RVd, and represents a convenient all-oral NCCN compendium–listed regimen for both transplant-eligible and ineligible patients who have difficulty with frequent medical appointments.

Most modern three-drug induction regimens do not include an alkylating agent, and investigations to find the superior IMiD and PI combination are ongoing. To that end, multiple phase II studies have demonstrated superior performance and a favorable toxicity profile for a triplet based on the next-generation PI carfilzomib[125–128] in combination with lenalidomide and dexamethasone (KRd). KRd therapy is associated with the rapid achievement of deep responses, down to the level of MRD negativity prior to the delivery of consolidation therapy, if utilized. In addition, a phase III trial exploring the need for high-dose melphalan consolidation therapy in the context of KRd or KCyD induction (the FORTE trial, NCT02203643) reported outstanding results with respect to MRD negativity rates, with or without consolidation therapy.[129] KRd is a NCCN compendium-listed regimen for upfront treatment in the United States and is a preferred regimen. Of note, although it has been compared to RVd in the phase III ENDURANCE trial[130] and found to result in comparable outcomes, the design of this trial and the large number of patients in both arms opting for "alternative therapy" (not defined) likely prevented superior outcomes from being demonstrated with KRd. In addition, the KRd regimen also differs from RVd with respect to a significantly decreased neuropathy risk, although adverse cardiovascular events can be more common with the use of KRd. For patients who will receive this regimen, a baseline EKG and echocardiogram as well as cardiac biomarkers including troponin, BNP, and/or NT-proBNP are warranted. Furthermore, in otherwise-fit patients with renal injury, carfilzomib-based platforms can also be utilized: the CYKLONE[131] regimen (cyclophosphamide, carfilzomib, thalidomide and dexamethasone) achieves deep responses, with excellent PFS and OS and minimal neuropathy, and the regimen of KCyD is also appropriate in selected instances.

Patients with newly diagnosed MM and renal injury represent a challenging and arguably underserved patient population. Since lenalidomide is renally cleared, its use is not feasible in most newly diagnosed patients who have significant kidney injury. CyBorD, also known as VCd, has been used for many years in this patient population. Akin to the EVOLUTION trial, the IFM 2013–04 study[132] asked whether a triplet containing an alkylating agent or an IMiD was superior, and compared bortezomib, thalidomide, and dexamethasone (VTD) to VCd. This trial showed superiority for VTD with respect to ORR and VGPR rates; VCd caused more hematologic toxicity while VTD caused significantly more neuropathy, as thalidomide carries significant neuropathy risk along with bortezomib. Both regimens are acceptable for induction therapy, as are the KCyD and the CYKLONE regimens described above.

Recently investigators have added the anti-CD38 monoclonal antibody daratumumab to existing induction regimens. Daratumumab (Dara) is a human anti-CD38 IgGκ monoclonal antibody that was initially FDA-approved in 2015 for myeloma patients who have had more than three relapses. Daratumumab binds CD38-expressing malignant plasma cells with high affinity and induces tumor cell death through diverse mechanisms of action, which include complement-dependent cytotoxicity; antibody-dependent, cell-mediated cytotoxicity; antibody-dependent cellular phagocytosis; and induction of apoptosis. Moreover, daratumumab suppresses Tregs and the actor enzyme activity-driven suppression of T cells via the adenosine signaling pathway. The phase III ALCYONE trial[133] studied a bortezomib, melphalan, and prednisone (VMP) regimen (which is safe in patients with renal impairment), with or without daratumumab in transplant-ineligible patients. This trial showed superior PFS and OS with the quadruplet regimen of daratumumab + VMP over VMP alone. Of note, also in transplant-ineligible patients, the MAIA trial[134] studied the doublet of lenalidomide and dexamethasone, with or without daratumumab (Rd, vs. DRd). This study showed higher CR rates, higher MRD negativity rates, and higher PFS rates for the triplet containing daratumumab, and this regimen is also now FDA-approved. Also of note is the ongoing LYRA study[135] for both transplant-eligible and -ineligible patients, which is evaluating the regimen of daratumumab with CyBorD (daratumumab + VCd) as induction with daratumumab maintenance for one year. Currently, the choice of DRd vs. daratumumab + VMP for transplant-ineligible patients is largely based on the patient's renal function, as well as access to medications and the drug toxicity profile.

More recently, the phase III CASSIOPEIA trial[75] has explored whether adding daratumumab to VTD would further improve outcomes in transplant-eligible patients, and showed that daratumumab + VTD therapy led to increased depths of response and PFS and was associated with a good safety profile. This regimen is now FDA-approved as the first four-drug induction therapy combining monoclonal antibody with IMiD, PI, and steroid, and is additionally also suitable for patients with renal insufficiency.

A number of groups are exploring the combination of daratumumab with even newer IMiD or PI platforms. To this end, the GRIFFIN trial[136] is studying RVd with or without daratumumab. The latest update as of this writing showed superior response rates and depth of response, including MRD negativity rates, for the daratumumab-containing quadruplet therapy arm. Even more exciting, an induction regimen, combining once-weekly KRd with daratumumab,[117] showed not only rapid responses, but also a VGPR rate greater than 97%, with nearly 80% of patients achieving an MRD negative state *without* consolidation high-dose therapy. Indeed, the MASTER trial,[137] which also studied daratumumab + KRd and a number of related regimens with the addition of HDM/ASCT consolidation, reported comparable MRD negativity rates, without obvious benefit from the HDM consolidation. These outstanding results have prompted the initiation of the multi-institutional ADVANCE trial (NCT04268498) to further investigate the cutting-edge quadruplet regimen of daratumumab + KRd. Finally, in May 2020 the FDA approved subcutaneous daratumumab (Darzalex Faspro) in MM based on results of the COLUMBA noninferiority trial; subcutaneous daratumumab is currently approved in combination with VMP, Rd, Vd, and as monotherapy. As it is priced comparably to intravenous daratumumab, the markedly improved convenience of drug administration and additionally improved safety of subcutaneous daratumumab is anticipated to further accelerate the use of this agent.

Because of daratumumab's excellent safety and toxicity profile and non-overlapping mechanism of action with that of other novel agents, the field is gradually shifting toward quadruplet induction therapy, adding daratumumab to the triplet of PI + IMiD + steroid, since these regimens are safe, and lead to rapid and deep responses, including MRD-negative CRs for newly diagnosed patients. As MRD negativity is an important proxy for a variety of important patient outcomes, we anticipate that the profound improvements in induction will also impact the use of HDM/ASCT as consolidation therapy in the future, as discussed below.

Indeed, with these modern regimens, properly diagnosed treated newly diagnosed MM has essentially a 100% ORR and an increasingly high CR and MRD negativity rate as well. True de novo primary refractory or primary progressive MM patients are extremely unusual even in high-volume myeloma centers, and such presentations warrant repeat pathologic confirmation of the underlying diagnosis. Rare newly diagnosed MM patients who are truly unresponsive to induction therapy have a poor prognosis, and the reader is referred to the section on Relapsed Disease for consideration of further treatment options.

Practical Considerations of Induction Therapy

Although definitive anti-myeloma therapy as described above should begin promptly, some patients may require "prephasing" or temporizing maneuvers. These maneuvers include pulses of steroids for hypercalcemia, pain, and other complications of disease for rapid palliation while the patient's diagnostic evaluation is completed and or emergent locoregional maneuvers, such as surgery or radiation, are delivered. While not ideal, the administration of high-dose steroids even prior to bone marrow sampling may be required in medical emergencies, which may include cord compression or related neurologic conditions, severe hypercalcemia, or fulminant renal failure.

In addition, for patients who will receive skeletal prophylaxis and will be exposed to anti-resorptive agents with induction therapy (see "skeletal protection"), dental "clearance" is useful. We refer patients to our dentistry colleagues with the request that major dental work (extractions, implants, etc.) which may increase the risk of osteonecrosis of the jaw and/or infectious complications be completed prior to initiation of anti-resorptive therapy if possible, and prior to initiation of systemic medical therapy for MM. This approach not only minimizes the risk of osteonecrosis of the jaw but may also reduce the risk of infectious complications following dental interventions during induction therapy when the patient is immunosuppressed. Indeed, while it is beneficial to start skeletal prophylaxis promptly, it is by no means mandatory to start this adjunctive therapy concomitantly with systemic medical therapy.

Finally, although tumor lysis syndrome is not commonly observed with the systemic therapy of myeloma, it can be useful to check a baseline serum uric acid level and glucose 6 phosphate dehydrogenase level (for administering rasburicase, if required) if the clinician judges the patient to have a high disease burden. In the authors' clinical practice, however, we do not routinely prescribe prophylactic allopurinol.

With respect to monitoring disease response, assessing toxicity, and treatment planning, it is common practice to obtain a complete blood count, comprehensive metabolic panel, magnesium, phosphorus, uric acid, LDH, β_2 microglobulin, serum protein electrophoresis (SPEP), serum immunofixation electrophoresis (SIFE), serum free light chains and ratio, and quantitative serum IgG/IgM/IgA such that the results are available on day one of each new therapy cycle which allows these results to be reviewed with the patient. The vast majority of patients can be assessed during therapy with spot urine studies for protein/creatinine ratio rather than repeated 24-hour collections, although an initial 24-hour urine collection for the protein/creatinine ratio, urine protein electrophoresis (UPEP), and immunofixation electrophoresis (UIFE), as well as analysis of urine light chains (if present) can be useful to establish a baseline. Finally, although the number of cycles of induction therapy varies across clinical trials and practitioners during routine practice, 3 to 8 cycles are commonly used in many MM trials. In general it is recommended to administer sufficient numbers of cycles of induction therapy to achieve the best response rather than identifying a defined number of cycles that are to be administered.

For transplant-eligible patients, early referral to a transplant center for counseling and planning is especially helpful. Most practitioners will plan for stem cell mobilization and collection by cycle 4 to 6 of induction therapy and/or after achieving at least VGPR. Importantly, continued lenalidomide exposure beyond 4 to 6 cycles of induction therapy may make peripheral blood stem cell collection more difficult. As a general rule, responding patients who plateau (e.g., at PR, VGPR) with measurable disease in the blood can be referred for HDM if required and eligible. There is no true upper limit on number of cycles that should be administered during induction therapy save for cumulative toxicities (generally decreased bone marrow reserve, cytopenias and neuropathy from a number of agents). In most cases, however, the patient is unlikely to obtain additional incremental benefit past 10 to 12 cycles of induction therapy with a given regimen.

For those patients who do achieve CR in the blood and urine, stem cell grafts for transplant-eligible patients should be collected. At this juncture, a repeat bone marrow examination with the addition of high-sensitivity MRD studies is warranted, if available. Such patients will typically have either very low levels of morphologically identifiable disease, or are in morphologic CR and are either MRD-positive or negative using the sensitive techniques described above. In the authors' practice, patients who have low but measurable amounts of morphologic disease in the marrow, and/or those who are MRD positive, can be offered 2 additional cycles of the same induction therapy to attempt to "clear" the marrow in order to achieve an MRD-negative status. Patients who fail to clear their marrow of disease and who are eligible may be considered for HDM/ASCT.

Although this is a practice which is being re-evaluated, most patients who achieve MRD negativity following induction therapy and who are transplant-eligible are offered the opportunity to collect and bank peripheral blood stem cells for possible early HDM/ASCT (see discussion below). Finally, with the current four-drug regimens, there are reports of very early MRD negative responses, as early as the end of cycle one or two of induction therapy. In these cases, there may still be measurable monoclonal proteins in the blood due to the long half-life of complete immunoglobulin molecules. Therefore, particularly when using highly effective induction regimens, MRD testing may be warranted in patients who have not reached serologic CR (i.e., are in VGPR). There is no clear guidance on how many induction cycles of therapy are truly needed for such patients, but we speculate that it may be possible to model therapy after PET-directed approaches for the management of classical Hodgkin lymphoma, where treatment with a defined number of cycles past demonstration of CR has been successfully used in a number of trials, with excellent outcomes.

Lastly, with respect to repeat imaging studies, we note that repeat cross-sectional imaging at the end of (successful) induction therapy, absent the development of new symptoms, is rarely necessary or useful and can be confusing, since not all lesions resolve even with highly successful therapy. In our practice, we repeat imaging typically with disease progression and/or the development of new or unexplained symptoms.

Skeletal Protection

Aminobisphosphonates, pamidronate, zoledronate, and more recently denosumab have all been extensively investigated in patients with MM and bone disease and have been shown to reduce skeletal complications and bone pain. Denosumab is a human monoclonal antibody that inhibits this maturation of osteoclasts by binding to and inhibiting RANKL. Researchers in a number of older randomized studies assessed their efficacy in patients with existing bone lesions and evaluated the development of new SREs. In this regard, pamidronate 90 mg and zoledronic acid 4 mg were equipotent in reducing bone-related complications.[138–140] In a large study, Medical Research Council (MRC) IX, investigators also evaluated the efficacy of zoledronic acid in a randomized comparison with clodronate and demonstrated the superiority of zoledronic acid in preventing new SREs in patients both with and without existing bone lesions. This trial also provided evidence that its continued use beyond 2 years was beneficial[141]; importantly, the study also suggested that zoledronic acid compared with clodronate, a first-generation bisphosphonate, improves OS, although it must be noted that the survival advantage was demonstrated with the use of older, less potent MM therapies. Pamidronate administration is also beneficial and has also been shown to produce responses or delays in disease progression in occasional patients. Whether a survival benefit for anti-resorptive bone agents remains in the modern era of potent therapies with combinations of novel agents is unknown.

Despite these benefits, two major toxicities of bisphosphonates have limited their use: renal impairment and osteonecrosis of the jaw. Osteonecrosis of the jaw is associated with dental infections for those having procedures following long-term use as well as the use of higher doses of anti-resorptive drugs that are delivered to MM patients. Patients with poor nutritional status, poor baseline dentition, and immunodeficiency may be at a higher risk. The frequency of these adverse events are between 3% and 5%. Given this, patients receiving bisphosphonates or denosumab require a thorough dental checkup before starting therapy with completion of all major dental work if possible (extractions, implants, etc.) and should have frequent dental follow-up with careful and conservative use of dental procedures. With these precautions, the frequency of osteonecrosis of the jaw has been reduced.

Similarly, the measurement of renal function before each bisphosphonate dose and the adjustment of the dose based on renal function also make use of bisphosphonates safer. For patients with renal insufficiency from any cause, denosumab is likely the safer agent. Finally, in the authors' clinical practice, a meaningful fraction of patients encounter significant and sometimes intolerable constitutional side effects associated with IV bisphosphonate therapy, including myalgias, arthralgias, fatigue, bone pain, and flu-like symptoms. A trial of both zoledronate and pamidronate may be warranted. However, patients who are intolerant of either may be candidates for denosumab. Indeed, in a large recent phase III trial,[142] denosumab was non-inferior to zoledronate for time to skeletal-related event in MM patients. Denosumab still carries the potential to cause osteonecrosis of the jaw but is associated with less renal toxicity and is much better tolerated in patients. With use of either class of anti-resorptive drugs, initial serial monitoring of serum calcium, phosphorus, and ionized calcium levels may be prudent, as hypocalcemia has been reported following the initial administration of anti-resorptive agents.

High-Dose Melphalan Therapy and Consolidation

In the era before the introduction of novel agents, and routine use of maintenance therapy, induction regimens, such as high dose dexamethasone, melphalan-prednisone, or VAD chemotherapy, rarely achieved CRs. In such a scenario, HDM/ASCT played a critical role in increasing CR and VGPR rates and prolonging the durability of unmaintained responses. The availability of novel agents and the use of maintenance therapy have dramatically changed this paradigm, with markedly improved rates of VGPR, CR, and even the MRD negative states at the end of induction therapy.

Because of the ever-shifting changes in induction regimens and use of maintenance therapy, many have questioned if modern regimens using novel agents can replace HDM and ASCT in the treatment of MM patients. This is an important question that has yet to be answered with a randomized trial, although critical trial results to date are reviewed below. Leading investigators are already asking whether patients who are MRD negative at the end of induction can defer HDM and proceed directly to maintenance, although most still advocate for stem cell collection and banking, thereby keeping HDM/ASCT available as an option as a later line of therapy. Nonetheless, at most centers in the United States HDM/ASCT is currently considered the standard-of-care "consolidation" for medically eligible patients after induction therapy. It is worth noting that although many efforts have been made to add agents to HDM to improve outcomes, convincing data at present showing that melphalan plus another agent is better than HDM alone is not available, and such regimens should not be used outside the context of a clinical trial.

Despite current practice by the overall MM treatment community, which offers HDM to essentially all eligible patients at the end of induction therapy, its role is changing in the modern era with increasing potent novel agents and high-sensitivity MRD monitoring, as well as greater awareness of both the acute and chronic toxicities associated with HDM therapy. The immediate down sides of HDM include both the cost and inconvenience of a relatively long inpatient hospital stay, mucositis and infection risk, risk of acute organ toxicities, as well as an arguably low but not-zero transplant-related mortality (TRM) rate.[143,144] Chronic effects include long-standing cytopenias, immunodeficiency, and pulmonary fibrosis among others, but most prominent are secondary malignancies,[145] particularly myeloid neoplasms[146,147] but also solid tumors. This secondary malignancy risk is compounded with the use of lenalidomide maintenance[148] and has gained even greater importance as a drawback of HDM therapy, as the OS of MM patients continues to improve.

The reader should note that although previously in fashion for certain high-risk patient populations, double or "tandem" autologous transplantation,[149] which represented prior interest in high-intensity induction therapy with a focus on cytotoxic agents, is no longer routinely practiced in the United States, due to the even greater toxicity associated with this approach, as well as improved response rates and depths of CR being achieved with induction regimens using the newer agents obviating the need for multiple rounds of HDM. Similarly, *allogeneic* stem cell transplantation alone, or after ASCT (the so-called "auto-allo"), carries a markedly higher rate of TRM than autologous transplantation, and is *not* the standard of care after induction therapy for newly diagnosed patients, essentially regardless of the depth of response. In the relapsed/refractory setting, highly selected patients may be considered for allogeneic stem cell transplantation,[150,151] if performed at a high-volume stem cell transplant center by specialized clinicians with expertise in allogeneic transplant for myeloma, ideally in the context of a clinical trial.

With respect to HDM and autologous transplant, the use of peripheral blood stem/progenitor cells mobilized with chemotherapy, granulocyte colony-stimulating factor (G-CSF), and/or plerixafor is the standard-of-care in MM, and bone marrow stem cells are rarely if ever used in the modern era. Surprisingly, multiple studies agree that the degree of tumor cell contamination in the collected stem cell product has no influence on transplant outcomes, and consistent with this, ex vivo manipulations to eliminate tumor cells within the graft have never demonstrated improvement in the depth of response, PFS or OS. Despite these observations, most practitioners will collect stem cells at or near the achievement of best antitumor response to induction therapy to minimize tumor cell contamination and the theoretical risks associated with re-introduction of neoplastic PCs. Because of potential difficulties with stem cell mobilization with cumulative use of alkylating agent exposure and lenalidomide e should be limited to insure an adequate stem cell harvests and complete hematopoietic recovery post-transplant. As a practical matter, achievement of VGPR or better response, and/or approximately 6 cycles of induction therapy are practical points at which stem cell collection can be performed, with additional cycles of induction therapy added after stem cell collection if appropriate.

Specific Trials of High-Dose Melphalan With Autologous Stem Cell Transplant

Because of the early discovery of melphalan's anti-myeloma activity and its evident dose-response relationship, HDM with ASCT has been studied extensively as consolidation therapy in newly diagnosed patients. The literature is confounded by the use of disparate and now oftentimes outdated induction regimens, inconsistent post-transplant maintenance therapy, and oftentimes durations of maintenance therapy that are now considered too short, and until very recently, lack of MRD assessments as part of the decision-making process and disease monitoring. Given this, we highlight only a few randomized clinical trials in the era of modern triplet therapy of IMiD, PI, and steroid.

The EMN02/HO95 trial[152] was a large multicenter randomized phase III study that used a proteasome (but not IMiD)-based backbone induction regimen, with randomization to ASCT (single or tandem) or VMP intensification, and an additional randomization to either RVD consolidation or no consolidation. This trial demonstrated PFS but no OS benefit for HDM/ASCT, but was limited by the use of relatively weak induction regimens.

The IFM/DFCI 2009 trial[82] randomized patients either to 8 cycles of RVd without high-dose therapy, as compared to 3 cycles of RVd, followed by HDM/ASCT, followed by 2 additional cycles of RVd post-transplant (for a total of 5 cycles). Both groups received lenalidomide maintenance, but its duration was limited to one year. This trial showed that for newly diagnosed transplant-eligible patients, HDM/ASCT provided a PFS but not an OS benefit, but interpretation of even these results is limited due to the short duration of lenalidomide maintenance (current practice is to continue maintenance therapy until disease progression). Additionally, this trial revealed that for MRD-negative patients at the beginning of maintenance therapy, PFS was excellent regardless of whether patients received HDM therapy; conversely, MRD-positive patients, including those who received ASCT, had inferior outcomes. What drives the difference in overall PFS is the *percentage* of patients achieving MRD-negative status at the beginning of maintenance therapy. The IFM/DFCI 2009 trial showed that in induction therapy with RVd, arguably already now a somewhat outdated regimen, HDM may help to improve the MRD negativity rates. Also of note, the ongoing phase III DETERMINATION trial has an identical study design except for administering lenalidomide maintenance therapy to progression; results are pending but as of early 2020 this trial has yet to meet its primary endpoint, which is to demonstrate a PFS or OS advantage for HDM/ASCT. This suggests that in addition to MRD status, prolonged maintenance therapy with lenalidomide, which is known to convert some MRD-positive patients to negativity, may abrogate the benefit of HDM/ASCT.

The second major randomized phase III trial of transplant with modern regimens is the FORTE trial.[129,153] This three-armed study used the potent PI carfilzomib, comparing 12 cycles of KRd without transplant ("KRd12"), versus 4 cycles of KRd plus HDM/ASCT and 4 additional cycles (total of 8), versus 4 cycles of KCyD plus HDM/ASCT and 4 additional cycles (total of 8). Patients were further randomized to maintenance therapy with carfilzomib monotherapy, or the doublet of carfilzomib + lenalidomide. When comparing the two most interesting arms, KRd12 versus KRd with HDM/ASCT, rates of MRD negativity were similar but PFS and OS data are still pending.

Lastly, the BMT CTN 0702 (STAMINA) trial[154] randomized patients to single ASCT tandem ASCT, or single ASCT followed by RVD × 4 cycles as consolidation, with all three arms proceeding with lenalidomide maintenance. This trial revealed single ASCT followed by lenalidomide maintenance to be non-inferior to the other two higher-intensity approaches with respect to PFS or OS.

In summary, the lack of benefit for HDM/ASCT as compared to the most potent commonly used current induction regimens (KRd), the advent of four-drug induction regimens which are expected to be even more potent than KRd induction, as well as evidence based on IFM/DFCI 2009 that MRD negativity during maintenance therapy is a strong predictor of favorable patient outcomes, and conversely the worrisome acute and chronic toxicities of HDM/ASCT, has given clinicians the impetus to pause and re-evaluate the current paradigm of offering HDM/ASCT as consolidation to all eligible patients. In the authors' practice, only patients who are morphologically positive or MRD positive at the end of induction therapy are encouraged to consider HDM/ASCT. For MRD-negative patients, it is reasonable to have an informed discussion with the patient and stem cell transplant colleagues, review existing data, and make an individualized decision as whether to proceed to HDM/ASCT.

Maintenance

Maintenance therapy is the use of ongoing lower-intensity therapy, most traditionally with a single agent, to eliminate or suppress remaining PC disease over a prolonged period. Previously, the standard of care for MM patients in first remission was observation with disease monitoring. However, a handful of practice-changing trials[155–158] published around 2012 and thereafter demonstrated clear benefits of oral lenalidomide maintenance therapy in both transplant-eligible and -ineligible MM patients, with all trials showing a PFS benefit and one trial showing an OS benefit.[156] Subsequent meta-analyses also demonstrated an OS benefit in multiple patient populations and treatment scenarios.[159–161]

Therefore, where available, maintenance therapy, with lenalidomide as the default drug, should be offered to patients, regardless of whether they received consolidation therapy and/or HDM/ASCT.[161] In the post-transplant setting, maintenance therapy is generally started after three months or on day 100, whereas patients not receiving HDM/ASCT can proceed directly to maintenance therapy. Ideally, maintenance should be initiated when the disease is in remission, at either undetectable or comparatively low levels, and in this clinical scenario, maintenance therapy can further deepen responses. For example, conversion of MRD positive to negative status can be observed, and this supports the notion that an additional antitumor response during the maintenance phase can be beneficial. Such observations call into question whether HDM/ASCT is in fact mandatory for patients who have a low disease burden at the end of induction therapy.

As a historical note, previous maintenance agents have included interferon alfa-2b and thalidomide, although these two drugs are no longer routinely used and will not be discussed further. Indeed, although many agents have been studied, data is strongest with lenalidomide as a maintenance agent (and lenalidomide is NCCN category 1 for both transplant-eligible and ineligible patients), with bortezomib probably being the next most-commonly used.

Immunomodulatory molecules are well suited for maintenance therapy because they can be administered orally at low doses for a prolonged period, with most patients tolerating such therapy well without undue side effects or cumulative toxicities. There have been three large randomized trials exploring the role of lenalidomide as maintenance therapy. Two of these studies were maintenance therapy after HDM/ASCT (CALGB100104[156,162] and IFM2005–02[157]), and the third study was in elderly patients receiving MP. All three studies showed improvement in PFS by 18 months; only the CALGB100104 randomized study showed improvement in OS. Of note, while there is general consensus as to the positive benefits of lenalidomide maintenance, its use after HDM/ASCT has been associated with higher rates of secondary malignancies, both solid tumors and hematologic, but most prominently MDS and AML. The relative risks and benefits of lenalidomide maintenance are worth discussing with patients who have received HDM/ASCT. This increase in secondary malignancies is *not* meaningfully observed with lenalidomide maintenance in patients not exposed to HDM/ASCT, whether due to medical ineligibility or preference.

Bortezomib has also been used in the maintenance setting. Generally, bortezomib maintenance has been restricted to clinical trials in which bortezomib was also used during the induction phase of the treatment. In the phase III HOVON-65/GMMG-HD4 trial, bortezomib maintenance seemingly improved the outcome in patients with high-risk karyotypic abnormalities.[163] As compared with induction regimens, bortezomib is usually given less frequently in the maintenance setting; different studies have used varying schedules of administration. In clinical practice, those patients who are intolerant of even low-dose lenalidomide, frequently due to constitutional side effects, may be considered for bortezomib maintenance. However, use of this agent is less convenient as it requires subcutaneous drug administration in the clinic. Based on the TOURMALINE-MM3 trial,[164] ixazomib oral therapy has also been used by some practitioners for patients on bortezomib maintenance who have irregular access to subcutaneous injections. The TOURMALINE-MM3 trial demonstrated a PFS but not OS benefit to the use of ixazomib maintenance therapy. Lastly, as a newer-generation PI with greater efficacy and lack of cumulative neuropathy, carfilzomib maintenance, either as monotherapy or combination therapy, is also highly attractive. In a phase II trial,[165] transplant-ineligible patients were induced with carfilzomib, cyclophosphamide, and dexamethasone (CCyD) with carfilzomib maintenance. This regimen showed excellent two-year PFS and OS rates. Another phase II trial by Zimmerman and colleagues[166] studied combination therapy in transplant-eligible patients, with KRd induction, HDM/ASCT, KRd consolidation, and then 10 cycles of KRd maintenance, for a total of up to 18 cycles of KRd. At the conclusion of this admittedly intensive regimen, an impressive 74% to 97% of patients were assessed to be MRD negative.

Finally, as the FDA has now approved induction regimens which include daratumumab, a number of investigators have naturally considered continuing this agent as first-line maintenance therapy, particularly for patients who are ineligible for or decline HDM/ASCT. Data confirming the efficacy of daratumumab monotherapy, albeit in the relapsed/refractory setting, come from the SIRIUS and GEN501 trials.[167,168] Daratumumab is an attractive maintenance agent with minimal toxicity, and a relatively convenient schedule being administered every 28 days. Although previously given solely by intravenous infusion, subcutaneous daratumumab administration was investigated in the COLUMBA trial,[169] and was recently approved by the FDA. This markedly more convenient route of administration is also associated with lower rates of reactions, further enhancing the feasibility of long-term daratumumab administration. As one of the newest agents to be used in this fashion, prospective data on outcomes with daratumumab maintenance after first-line therapy remain limited at present, although the phase 2 LYRA study[135] is administering daratumumab maintenance to both transplant-eligible and -ineligible patients after induction, with preliminary results showing deepening of responses throughout the maintenance phase. Finally, although single-agent maintenance or doublet maintenance (with steroid) is commonly used, investigators have also studied multi-agent combination therapy in the maintenance setting. Investigators at Emory have studied RVd as a combination consolidation/maintenance regimen[170] in high-risk transplant-eligible patients after HDM/ASCT. For this patient population, this combination regimen achieved high rates of VGPR and good results for PFS and OS.

Having considered all of the above, most patients at present should be treated with single-agent maintenance in the United States, with lenalidomide the default choice. Bortezomib, carfilzomib, daratumumab, or other agents can be used but generally on an individualized basis. Multi-agent combination therapy in the maintenance setting should likely be reserved for the highest-risk patients. Finally, although many patients will stop maintenance therapy due to biochemical or symptomatic relapse of MM, a fraction of patients, most on lenalidomide maintenance, remain MRD negative for a prolonged period of time, often many years. The optimal duration of maintenance therapy in such patients is unknown, and therapeutic discontinuation with close monitoring, built on the model of tyrosine kinase inhibitor discontinuation in chronic myeloid leukemia with highly sensitive disease monitoring, is now an emerging area of investigator interest for this fortunate patient population.

RELAPSED DISEASE

Managing Relapsed Multiple Myeloma

Despite the significant improvements in PFS/OS outcomes for MM with the introduction of PIs and IMiDs, the vast majority of patients experience relapse during their disease course.[171,172] Relapse is defined as the reappearance of signs and symptoms of the disease or signs of increasing disease and/or end-organ dysfunction that are related to the underlying MM.[173] When patients present with overt clinical symptoms, the relapse is referred to as *clinical* relapse whereas if the relapse is determined by increase in MM protein studies in the absence of new symptoms, then it is termed a *biochemical* relapse. Upon disease relapse, there are a number of factors to be weighed before selecting therapies (Table 91.8).

Disease-Related Factors

The most important question to ask is when to start new therapy in a relapsing MM patient. The current approach for newly diagnosed MM is to provide continuous therapy in the form of maintenance for both transplant-eligible and -ineligible patients.[160,174] Since maintenance therapy continues until relapse or the development of unacceptable toxicities in most cases, patients may relapse either on therapy or during a drug holiday—this will influence the choice of regimen and the timing to initiate the next line of treatment. The duration of maintenance therapy and/or time off maintenance therapy, as well as the duration of time since completion of the initial induction therapy and/or HDM/ASCT should also be considered when making this decision. Regardless of whether the relapse occurs on or off therapy, the timing of starting therapy can also pose a challenge: if the relapse is associated with clinical features (e.g., symptomatic anemia, new bone pain, expanding or new plasmacytomas, hyperviscosity, etc.), immediately starting the next line of treatment is clearly indicated. Conversely, for a biochemical relapse, the pace of relapse is important and the IMWG has defined criteria indicating the need for treatment initiation[71]: the doubling of monoclonal protein characterized by an increase in the absolute levels of monoclonal protein of greater than 1 g/dL in serum or of greater than 500 mg per 24 hours in urine, or involved free light chain level by more than or equal to 20 mg/dL (plus an abnormal FLC ratio) in two consecutive measurements separated by ≤2 months. Keeping these criteria in mind, the decision to start a patient with a biochemical relapse on therapy should be individualized, and made based on a risk-benefit analysis keeping in mind the patient-related and therapy-related factors discussed below. If, however, a patient is rapidly progressing and has symptomatic disease, the therapy should match disease intensity. High-risk karyotypic abnormalities, EMD, circulating plasma cells, high R-ISS stage at relapse, poor response to earlier therapies, rapid progression while on maintenance or after earlier lines of therapy, and related factors may all justify the use of aggressive therapies for rapid disease control regardless of whether the relapse is clinical or biochemical.

As a general rule, in the typical patient the majority of relapse regimens can be initiated at the full doses and continued until progression or intolerance occur. However, treatment holidays or dose reductions for toxicity are not uncommon for many patients, particularly in later lines of therapy, and practitioners may commonly need to modify regimens via dose reductions, temporary treatment holidays, or occasionally deviating from prescribed dosing schedules, thereby customizing a given regimen for each patient. This can maximize the benefits of a relapse regimen while minimizing toxicities, and help the patient to obtain the maximum potential benefit from each drug or drug combination before the next line of treatment is needed.

Finally, on occasion a symptomatic plasmacytoma in the setting of relapsed disease may require a short course of radiation therapy or in rare cases, surgical intervention; however, it is important to remember that the goal of local therapy in this setting is palliation of local symptoms only and should ideally not unduly delay systemic therapy.

TABLE 91.8 Factors to Consider in Selecting Therapy for Patients With Relapsed Myeloma

Patient-Related	Disease-Related	Therapy-Related
• Age • Performance status • Renal insufficiency • Poor marrow reserve • Neuropathy • Frailty and comorbidities • Social support for clinic and infusion visits	• Cytogenetics: presence of high-risk features such as del (17p), t(4;14), t(14;16) • Nature of relapse • Clinical vs. biochemical • Presence and extent of end organ damage • Extramedullary disease • Plasma cell leukemia	• Previous therapy • Depth of response • Duration of response • Route of administration (IV, SC, PO) • Cost • Residual toxicity from previous therapies • Myelosuppression • Neuropathy • Thrombosis • Risk of second primary malignancies

IV, Intravenous; *PO*, per oral; *SC*, subcutaneous.

Patient-Related Factors

The individual patient's performance status and comorbidities can play a critical role in determining optimal therapy (see Chapters 157 and 158). Although age can be a factor determining tolerance to therapy, frailty appears to be more important in predicting survival in MM.[175] Indeed, patient-related factors play a very important in the decision-making for optimal therapy for both newly diagnosed and relapsed MM. In either setting, the goal of therapy is to achieve a deep and durable response, and to alleviate or prevent sequelae of the disease. The clinician also must bear in mind patient preferences, socioeconomic considerations, and logistics in choosing between oral and parenteral therapies, as well as dosing schedule. For example, a patient who has a longer commute to the clinic to receive parenteral therapies may elect to pursue an all-oral regimen when efficacy and safety are comparable. Similarly, medication co-pays and insurance considerations may influence some patients' choice of therapy.

Treatment-Related Factors

There are several issues related to prior therapies received that need to be taken into consideration when approaching a relapsed and/or refractory MM patient. First, it is important to decide whether a patient's MM is refractory to a certain agent or class of drugs, and whether they can be retreated with that same agent or drug class. Refractory disease is defined as MM that is nonresponsive while on therapy or progresses within 60 days of last therapy as per IMWG criteria.[71,173] However, it is also important to consider the dosing and schedule of the agents or drug classes used at the time. For example, one patient progressing on standard RVd induction dose and schedule may be different than another progressing on either dose-attenuated lenalidomide and/or bortezomib maintenance. For example, whether a patient who has progressed on standard RVd with lenalidomide at 25 mg daily, versus another patient progressing on lower doses of a drug (e.g., lenalidomide 10 mg daily as monotherapy, arguably the most common maintenance regimen) should both be considered "lenalidomide refractory" needs to be considered on a case-by-case basis. Some practitioners may choose to rechallenge a patient progressing on attenuated doses of a drug with the full dose of that same agent, oftentimes in combination, before concluding that the disease is truly refractory.

In general, if the patient has previously responded well to an agent or drug class without major toxicities, one might consider retreatment with the same agent or another in the same drug class. Response rates with re-treatment, however, are generally lower, and the duration of response is commonly decreased. For example, in a phase II study of bortezomib with or without dexamethasone[176] retreatment for patients relapsing ≥ 6 months after prior bortezomib-based therapy, the ORR was 40% and median time to progression (TTP) merely 8.4 months. In addition, retreatment may be a suboptimal approach in a patient with aggressive disease where other novel effective therapies with differing mechanisms-of-action are available. Given this, a lack of response or a short duration of response to a particular agent or class of drugs in the past would generally lead to the use of non-cross-resistant agents or drug classes. Next, toxicities to previous drug regimens should be considered when deciding future therapies. For example, someone who had severe GI side effects or neuropathy (especially persistent symptoms after drug discontinuation) would not be an ideal candidate for a bortezomib-based or thalidomide-based salvage regimen. In the case of overlapping toxicities, it is helpful to ascertain where possible if the toxicity was due to multiple agents or one particular agent that can be avoided in the future. The depth and duration of response following a previous HDM/ASCT is also important when considering a salvage transplant (discussed below).[177]

Clinical Trials in Relapsed Multiple Myeloma

Several large phase II and III randomized clinical trials have been conducted in patients with relapsed myeloma. These studies have resulted in the approval of several new regimens for the treatment of relapsed myeloma since 2012, including eight new drugs (carfilzomib, daratumumab, isatuximab, ixazomib, panobinostat, pomalidomide, Selinexor, belantamab mafodotin) for relapsed MM patients with one or more prior lines of therapies (Tables 91.9 and 91.10). There are nuances in the patient populations that enrolled on each of the trials and the tables summarize the clinical trial patient populations to better inform the optimal treatment choice for a given patient.

Carfilzomib is a selective and irreversible PI which is administered intravenously. In a large, open-label, single-arm phase II study,[178] 266 patients with relapsed myeloma progressing on their prior therapy were treated with carfilzomib at 20 mg/m^2 during cycle 1 and thereafter at 27 mg/m^2 intravenously twice weekly for three of four weeks. Patients were refractory or intolerant to both bortezomib and lenalidomide. The ORR was 23.7% with a median duration of response of 7.8 months and a median OS of 15.6 months. Common adverse events included fatigue, anemia, and thrombocytopenia. A small proportion of patients (<5%) experienced grade 3 or 4 dyspnea, acute renal failure, and heart failure.

In the ENDEAVOR trial,[167,179] dose-intense carfilzomib/dexamethasone (Kd) was more efficacious than bortezomib/dexamethasone (Vd) with improvement in the ORR (77% vs. 63%) as well as doubling of CR rate (13% vs. 6%) and median PFS (18.7 months vs. 9.4 months). Because the median follow-up time was short (1 year), there was no survival advantage noted. Anemia, dyspnea, and cardiac failure were the most common grade 3/4 adverse events in the Kd group, whereas diarrhea and peripheral neuropathy were more common in the Vd arm.

ASPIRE was a large, randomized phase III trial[180] comparing carfilzomib, lenalidomide, and dexamethasone (KRd; 396 patients) with lenalidomide and dexamethasone (Rd; 396 patients) in patients with relapsed MM who had received one to three prior treatments. PFS was significantly improved in the KRd arm compared with the Rd arm (26.3 months vs. 17.6 months; hazard ratio for progression or death, 0.69; $P = .0001$). The KRd arm had an ORR of 87.1% compared with 66.7% in the Rd arm ($P < .001$). There was an increased incidence of grade 3/4 adverse events such as hypokalemia, thrombocytopenia, hypertension, and cardiac failure in the KRd arm. The median OS was not reached in either group at the time of the interim analysis, however after 67.1-month follow-up[181] the median OS was 48.3 months (95% CI, 42.4 to 52.8 months) for KRd versus 40.4 months (95% CI, 33.6 to 44.4 months) for Rd (hazard ratio, 0.79; 95% CI, 0.67 to 0.95; one-sided $P = .0045$).

PANORAMA-1[182] was a large, multicenter, international, randomized, placebo-controlled, double-blind phase III trial for patients with relapsed MM who had received between one and three prior regimens. Patients were randomly assigned to receive panobinostat + Vd (387 patients) or placebo + Vd (381 patients). The median PFS was 12 months for the panobinostat group and 8 months for the control group. The median follow-up was 6 months, and there was no difference in the OS at the time of publication of the results. There was an increased incidence of grade 3/4 adverse events such as

thrombocytopenia, diarrhea, asthenia, or fatigue and peripheral neuropathy in the panobinostat arm.

TOURMALINE-MM-1[183] was a phase III study comparing the oral PIs ixazomib, lenalidomide, and dexamethasone (IRd; 360 patients) with placebo, lenalidomide, and dexamethasone (Rd; 362 patients) in patients with relapsed/refractory myeloma who failed one to three prior regimens. After a median follow-up of 14.7 months, the IRd group had a PFS of 20.6 months compared with the placebo group, which had a PFS of 14.7 months (hazard ratio for disease progression or death in the ixazomib group, 0.74; $P = .01$). The ORRs were 78% in the ixazomib group and 72% in the placebo group. The median OS has not been reached in either group after 23 months. Diarrhea, rash, and thrombocytopenia were the more common grade 3/4 adverse reactions associated with the IRd group compared with the placebo group.

Pomalidomide (Pom) is a third-generation IMiD that is more potent than lenalidomide. In a multicenter, open-label, randomized phase II study,[184] the efficacy and safety of pomalidomide with or without low-dose dexamethasone (Pomd) was studied in 221 patients who had relapsed MM after two or more lines of prior therapy and were progressing on the last therapy. The ORR was 33% for patients receiving Pomd and 18% for patients receiving pomalidomide alone with median response durations of 8.3 and 10.7 months, median PFS rates of 4.2 and 2.7 months, and OS of 16.5 and 13.6 months, respectively. Refractoriness to lenalidomide or resistance to both lenalidomide and bortezomib did not affect the outcomes with pomalidomide and low-dose dexamethasone. Grade 3/4 neutropenia (41%), anemia (22%), and thrombocytopenia (19%), as well as pneumonia (22%), were the predominant adverse events encountered. An international, randomized, open-label phase III trial compared Pomd (302 subjects) with high-dose dexamethasone (153 subjects) in patients with refractory MM after two lines of chemotherapy containing bortezomib and lenalidomide.[185] After a median follow-up of 10 months, the median PFS was 4 months for patients receiving pomalidomide and dexamethasone versus 1.9 months for high-dose dexamethasone alone. The most common grade 3/4 hematologic adverse events in the pomalidomide arm were neutropenia, anemia, and cytopenias. Nonhematologic adverse events (grade 3/4) included pneumonia and fatigue. The OPTIMISMM trial[186] was a randomized, open-label phase III study comparing pomalidomide, bortezomib, dexamethasone (Pom-Vd; 281 patients) compared to Vd (278 patients) for patients who have received 1 to 3 prior lines of therapies. The study met its primary endpoint after a 15.9-month follow-up, showing improved PFS in favor of Pom-Vd with median 11.2 months compared to 7.1 months for Vd arm (hazard ratio 0.61, 95% CI 0.49 to 0.77; $P < 0{\cdot}0001$). The ORR was 82.2% for the Pom-Vd arm whereas it was 50% for the VD arm. The most common grade 3 or 4 treatment emergent AEs were neutropenia (42% vs 9%), infections (31% vs 18%), and thrombocytopenia (27% vs 29%).

Elotuzumab (Elo) is an immunostimulatory monoclonal antibody targeting SLAMF7. Elotuzumab directly activates natural killer cells through both the SLAMF7 pathway and Fc receptors; it also targets SLAMF7 on myeloma cells and facilitates the interaction with natural killer cells to mediate the killing of MM cells through antibody-dependent cellular cytotoxicity ADCC. The drug showed activity in combination with lenalidomide and dexamethasone in a phase IBM-II study of patients with relapsed/refractory myeloma.[187] Elo was further evaluated in an open-label, international, randomized, multicenter phase III trial known as the ELOQUENT-2 trial.[188] The two arms of the trial consisted of Elo, lenalidomide, and dexamethasone (Elo-Rd; 321 patients) and lenalidomide and dexamethasone (Rd; 325 patients). The rate of PFS at 1 year (after a median follow-up of 24.5 months) in the Elo-Rd group was 68%, as compared with 57% in the Rd group. Moreover, at 2 years, there was a 41% PFS advantage in the Elo-Rd group compared with 27% in the Rd group. The median PFS was 19.4 months in the Elo-Rd group versus 14.9 months in the Rd group (hazard ratio for progression or death in the elotuzumab group, 0.70; $P < .001$). ORRs varied between the two groups: 79% in the Elo-Rd group and 66% in the Rd group. Prespecified interim analysis for OS indicated a strong trend ($P = .0257$) in favor of the Elo-Rd arm compared with the Rd arm with early separation sustained over time (43.7 months vs. 39.6 months, respectively; hazard ratio, 0.77). Of the patients in the Elo-Rd group, 10% had infusion reactions. Other grade 3/4 adverse events in the Elo-Rd arm were lymphocytopenia and fatigue. A combination of elotuzumab with pomalidomide and dexamethasone (Elo-Pomd) was also compared with pomalidomide dexamethasone in a randomized phase II trial,[189] leading to the FDA approval of this combination.

Daratumumab (Dara) is a human anti-CD38 IgGκ monoclonal antibody that was initially FDA-approved in 2015 for myeloma patients who have had more than three relapses.[190] The ORR was 31% among 148 patients treated with daratumumab at 16 mg/kg; the median response duration was 7.4 months, PFS was 3.7 months, and OS was 20.5 months.[190] Dara was well tolerated; fatigue and anemia were the most common adverse events.

The POLLUX trial[77] was a phase III study comparing daratumumab, lenalidomide, and dexamethasone (Dara-Rd; 286 patients) with lenalidomide and dexamethasone (Rd; 283 patients) in patients with at least one prior line of therapy. After a median follow-up of 13.5 months, the estimated median PFS was not reached in the Dara-Rd group compared with 18 months in the lenalidomide and dexamethasone group. The ORR was superior in the Dara-Rd arm (92.9%) compared with Rd (76.4%), as was MRD negativity via NGS at the 10^{-5} threshold (22.4% vs. 4.6%). The most common ≥grade 3 AEs during treatment were neutropenia (Dara-Rd = 51.9%, Rd = 37%), thrombocytopenia (Dara-Rd = 12.7%, Rd = 13.5%), and anemia (Dara-Rd = 12.4%, Rd = 19.6%). The CASTOR trial[76] was a phase III study comparing daratumumab, bortezomib, and dexamethasone (Dara-Vd; 251 patients) with Vd (247 patients) in patients with at least one prior line of therapy. The primary endpoint of PFS was met after a 7.4-month follow-up, showing median PFS of 16 months on the Dara-Vd arm, whereas that of the Vd arm was 7.2 months. The ORR was higher in the Dara-Vd arm compared to the Vd arm (82.9% vs. 63.2%, $P < .001$). The most common ≥grade 3 AEs in the Dara-Vd and the Vd arms were thrombocytopenia (45.3% and 32.9%, respectively), anemia (14.4% and 16.0%, respectively), and neutropenia (12.8% and 4.2%, respectively).

The EQUULEUS trial[78] was an open-label multicenter trial that studied the combination of daratumumab, pomalidomide, and dexamethasone (Dara-Pomd) in patients who have received two more prior lines of therapy (103 patients). The safety profile of Dara-Pomd was similar to that of pom-dex alone, with the exception of a higher incidence of neutropenia without an increase in infection rate. The ORR was 60% and among patients who achieved a CR, 29% were MRD negative at the 10^{-5} threshold. After a median follow-up of 13.1 months, the median PFS was 8.8 months and median OS was 17.5 months. The CANDOR trial[191] was a randomized, phase III study that compared daratumumab, carfilzomib, and dexamethasone (Dara-Kd; 312 subjects) with Kd (154 subjects) in patients who have received at least one prior line of therapy, with PFS as the primary endpoint. After a median follow-up of 16 months, the primary endpoint was met with Kd showing PFS of 15.8 months whereas that for Dara-Kd was not reached. The ORR and MRD negative CR rates were superior in the Dara-Kd arm (84.3% vs 74.7%, 13.8% vs 3.2%, respectively).

Isatuximab (Isa) is a chimeric IgG kappa monoclonal antibody that targets CD38[192,193] that has been examined both as a single agent and in combination therapies in relapsed MM patients. Two large, randomized phase III trials have recently been reported with this monoclonal antibody in combination with Pomd and Kd. ICARIA was a randomized phase III trial[194] that compared Isa-Pomd (307 subjects) with Pomd (153 subjects) for patients with one prior line of therapy, which met its primary endpoint of median PFS improvement with Isa-Pomd (11.5 months vs. 6.5 months) after a median follow-up of 11.6 months. IKEMA was a randomized phase III trial[195,196] comparing Isa-Kd (179 patients) with Kd (123 patients) in patients with 1 to 3 prior lines of therapy. After a follow-up of 20 months, the primary endpoint was reached showing PFS not being reached in the Isa-Kd arm whereas it was 19.15 months for the Kd arm. There were no differences seen between ORR between the two arms of this study (86.6% vs 82.9%), and the safety profile appeared similar as well.

Selinexor is a first-in-class selective inhibitor of nuclear exportin protein "exportin-1 inhibitor" (XPO1, CaRM1). It works by binding to exportin 1 and blocking the transport of a number of regulatory proteins that are involved in MM cell growth from the nucleus to the cytoplasm. This blockade leads to cell cycle arrest and apoptosis.) Selinexor t has shown preclinical activity in several solid and hematologic cancer models.[197] Selinexor was combined with dexamethasone in the STORM trial,[198] a single arm phase IIb study (122 patients), in patients who had received at least III prior therapies including PI, IMiD, and an anti-CD38 monoclonal antibody. The ORR was 26%, median PFS was 3.7 months, and median OS was 8.6 months.

Belantamab mafodotin is a first-in-class antibody drug conjugate (ADC) consisting of an anti- BCMA antibody conjugated to the cytotoxic payload of monomethyl auristatin F, an anti-neoplastic that blocks tubulin polymerization. BCMA is a protein that is almost universally expressed by MM cells. In the DREAMM-2 trial[56] of single-agent belantamab mafodotin in MM patients refractory to PI, IMiD, and anti-CD38 therapy, it showed a response rate of 31% to 34% ($n = 196$, median 6 prior lines of therapy) with two dosing strategies (2.5 mg/kg, 3.4 mg/kg). However, the drug moiety appears to cause ≥grade 3 keratopathy in 42% to 46% of the patients and lower doses are being explored in drug combination clinical trials.

Role of Salvage Autologous and Allogeneic Stem Cell Transplant

The role of salvage ASCT is less clear compared with the data in the front-line setting. However, the American Society for Transplantation and Cellular Therapy, the European Society of Blood and Marrow Transplantation, and the IMWG have developed consensus guidelines based on best evidence regarding use of salvage HDM/ASCT in relapsed MM.[177] They recommend that salvage transplant be considered for relapsed MM patients who are transplant eligible but have not received a transplant as part of first-line therapy, or in patients who relapsed after first-line therapy including HDM/ASCT and who achieved an at least 18-month PFS. In one phase III study performed in the UK,[199] patients with relapsed MM after at least 18 months after prior HDM/ASCT were randomized to induction therapy with bortezomib, doxorubicin, and dexamethasone followed by either ASCT (melphalan 200 mg/m^2 preparative regimen) or oral cyclophosphamide (400 mg/m^2 per week for 12 weeks). The study showed an improved PFS in the auto-SCT group compared to oral cyclophosphamide (19 months vs. 11 months) but has been criticized for the choice of oral cyclophosphamide as a control since it is not widely used as a single agent in this setting. It appears that PFS duration after the first ASCT is predictive of outcomes after the second, salvage ASCT.[200–202] Although the PFS benefit being achieved with many regimens utilizing novel agents in the relapsed setting appears better than that of a second ASCT, this maneuver may still have a role in select cases. Furthermore, it remains relevant globally as many regions either do not have access to most novel agents or patients are unable to afford them.

The role of allogenic stem cell transplant is yet more controversial and requires more prospective studies in the era of modern MM therapy, given the numerous novel agents now available. There is one single arm phase II trial that treated 49 patients with melphalan (140 mg/m^2), fludarabine (90 mg/m^2), and antithymocyte globulin (ATG; 60 mg/kg body weight) conditioning followed by an unrelated donor transplant graft.[203] Although the ORR was 95% (including 46% CRs), the 1-year treatment related mortality (TRM) was 25%. At 43 months of follow up, the 5-year PFS and 5-year OS were reported at 20% and 26%, respectively. Given the efficacy of the novel regimens and the high TRM of this therapeutic modality, allogeneic stem cell transplant in relapsed/refractory myeloma should primarily be considered for young, fit patients with higher-risk disease, ideally in the context of a clinical trial, and such patients should regardless be treated by expert transplant physicians with substantial experience in allogeneic transplantation for myeloma.

Practical Approach to the First Relapse

The clinical trials summarized above included patients with a variety of patient-specific, disease and treatment features. One needs to take into account each of these factors in order to select the best therapeutic options for a given patient. The following are general guidelines on which options may be considered for each category of MM patient relapse below:

Bortezomib and Lenalidomide Sensitive: Essentially, all combination regimens in Tables 91.9 and 91.10 are applicable for these patients.

Bortezomib Sensitive/Lenalidomide Resistant: Most of the bortezomib or carfilzomib-based options (such as Dara-Vd, Dara/Pom/Dex Pom-Vd, Kd, etc.) would be reasonable options based on availability and patient preferences.

Bortezomib Resistant/Lenalidomide Sensitive: Any of the lenalidomide-based regimens (KRd, IRd, Elo-Rd, DRd, etc.) would be options for these patients, with perhaps the PI/IMiD-based combinations being preferred for patients with high-risk cytogenetics. Patients with resistance to bortezomib may nonetheless respond favorably to the newer-generation agent carfilzomib.

Bortezomib and Lenalidomide Resistant: This is a challenging population and commonly represents patients who achieved relatively unsatisfactory responses to, or those who progressed quickly on common PI/IMiD-based first-line therapies. Here, several regimens (Dara-Pomd, Isa-Pomd, Dara-Kd, Elo-Pomd, Kd, etc.) may be active. Belantamab mafodotin-blmf, a novel anti-BCMA ADC, is now also approved for patients who have been treated with at least four anti-myeloma agents, including PI, IMID, and anti-CD38 antibody. In addition to the above, a salvage second ASCT may be an option where access to novel agents is a practical impediment (see below). Moreover, salvage ASCT may be considered for a young, fit, high-risk patient with bortezomib-/lenalidomide-resistant disease.

Approach to Second Relapse and Beyond

A majority of patients who are relapsing for the second time have been exposed to both PIs and IMiDs, and a significant fraction in the modern era will also have been challenged with an anti-CD38 monoclonal antibody. As mentioned above, patients who are refractory to PI, IMiD, anti-CD38 antibody, and a fourth agent are eligible for belantamab mafodotin. However, the following are general guidelines of picking the most appropriate regimen for these patients.

Carfilzomib, Pomalidomide and anti-CD38 Monoclonal Antibody Sensitive: Most non-bortezomib-/non-lenalidomide-based regimens would be useful in this situation (Dara-Kd, Dara-Pomd, Elo-Pomd, Isa-Pomd, Isa-Kd, Kd, Dara monotherapy, etc.).

Carfilzomib Refractory/Pomalidomide and Anti-CD38 Monoclonal Antibody Sensitive: Here, most pomalidomide-based regimens would be applicable (Dara-Pomd, Elo-Pomd, Isa-Pomd, etc.) except Pom-Vd as these patients are now PI refractory.

Pomalidomide Refractory/Carfilzomib and Anti-CD38 Monoclonal Antibody Sensitive: Here, most carfilzomib-based regimens would be applicable (Dara-Kd, Isa-Kd, Kd etc.).

Carfilzomib and Pomalidomide Refractory/anti-CD38 Monoclonal Antibody Sensitive: Dara as monotherapy would be a relevant option in this scenario, as well as participation in clinical trials.

Carfilzomib, Pomalidomide Refractory, Anti-CD38 Monoclonal Antibody Refractory: Seli-Dex would be the most relevant approved option in this scenario, although clinical trial participation with novel immunotherapies may be the best option. Selinexor is approved for patients who have received at least four prior therapies, and are refractory to at least two PIs, two IMiDs, and an anti-CD38 antibody. Finally, a salvage ASCT may be an option where access to novel agents is a practical impediment. In addition, an allogeneic stem cell transplant may be considered for a young, fit, high-risk relapsed MM.

Investigational Therapies in Relapsed and/or Refractory Disease

A number of small molecules and immune therapeutics in clinical trials are showing promising results in terms of both safety and efficacy for relapsed myeloma (Table 91.11). Therapeutic targeting is geared toward the malignant plasma cell biology as well as modulation of the immune repertoire and the bone marrow microenvironment. More recently, focus of the field has shifted from predominantly small molecule development to more immunotherapy-based approaches. However, among the small molecule options, the drug classes that are further ahead in development include novel PIs, cereblon E3 ligase modulators (or CELMoDs), and BCL-2/MCL1 pathway inhibitors. CELMoDs are functionally different from the IMiDs. They are larger molecules and work by quickly degrading a specific set of proteins (Ikaros and Aiolos). They are potent modulators of the cereblon E3 ligase complex. They also stimulate the immune system and kill myeloma cells directly, even when myeloma has become resistant to other therapies. Among the novel PIs, early phase data with both oprozomib[204,205] and marizomib[206] show clinical activity but safety has been a concern, with gastrointestinal adverse events for oprozomib and central nervous system side effects for marizomib being dose-limiting toxicities. The oral CELMoDs CC-220[207] and CC92480[208] have recently been reported to be active even in patients who have become refractory to both lenalidomide and pomalidomide. These and other CELMoDs are now being studied in combination with other novel agents in clinical trials for relapsed MM. Lastly, the Bcl-2 inhibitor venetoclax has demonstrated both single-agent activity[209] and good synergy with bortezomib and dexamethasone,[210] especially in the patients with the t(11;14) translocation and Bcl-2 overexpression. A randomized phase III trial is underway to compare venetoclax-Vd versus Vd in relapsed MM patients with one or more prior lines of therapy.

With respect to immune therapy for MM, chimeric antigen receptor T cells have been examined in early phase clinical development targeting BCMA for relapsed MM patients. An initial proof-of-concept study from the NCI reported clinical activity in heavily pretreated patients[211] but observed high grades of cytokine release syndrome (CRS) and neurotoxicity. Subsequently, the bb2121 construct (idecabtagene vicleucel) has shown impressive clinical activity in advanced relapsed/refractory MM patients ($n = 128$, median 5 prior lines of therapy), with ORR of 73%, median PFS of 8.8 months, and median DoR of 10.7 months[212] [46]. CRS was seen in 84% of the patients (≥ grade 3 = 5%). Similarly, neurotoxicity was seen in 18% of patients (≥ grade 3 = 3%). The JCARH125 construct[213] (orvacabtagene autoleucel) phase I/II trial reported an ORR of 92% in heavily pretreated relapsed MM patients ($n = 62$), with 36% CR or better rates. The CRS rate was 89% (≥ grade 3 = 3%), while the neurotoxicity rate was 13% (≥ grade 3 = 3%). The JNJ-4528 construct[214–216] phase I recently reported on ORR of 100% ($n = 29$) with very high sCR rate (86%), but did not report the median PFS due to the short follow-up. The CRS rate was 93%, grade 3 or higher making up 7%, whereas neurotoxicity was observed in 10% (≥ grade 3 = 3%). Idecabtagene vicleucel (Abecma) was approved in March of 2021 for the treatment of adult patients with relapsed or refractory MM after four or more prior lines of therapy, including an immunomodulatory agent, a proteasome inhibitor, and an anti-CD38 monoclonal antibody. Other surface marker targets are also being explored as immunotherapeutic targets (see Table 91.11).

The antibody-based approaches being explored in clinical trials for relapsed MM include naked antibodies, ADCs, and bispecific antibodies. As mentioned above, the BCMA-ADC belantamab mafodotin has received accelerated FDA approval with a number of other drug conjugates in trials. There are several BCMA-directed bispecific monoclonal antibodies that have been recently evaluated. A phase I

TABLE 91.11 **Investigational Therapies**

B-Cell Maturation Antigen (BCMA) Directed Therapies

- Naked antibodies: SEA-BCMA
- Antibody-drug conjugates: MEDI2228, CC-99712, HDP-101,
- Bispecific antibodies: AMG-420, AMG-701, Teclistamab, PF-06863135, TNB-383B, REGN5458, CC93269
- Chimeric antigen receptor T cells: BB2121, BB21217, JNJ-4528, JCARH125, ALLO-715, LCAR-B38M, P-BCMA-101, CT-053, MCARH171, BRD015, CT103A
- Chimeric antigen receptor NK cells: CAR-NK92

GPRC5D Directed Therapies

- Bispecific antibodies: talquetamab, GPRC5D TRAB
- Chimeric antigen receptor T cells:

Signaling Lymphocytic Activation Molecule F7 (SLAMF7) Directed Therapies

- Antibody-drug conjugates: ABBV-838
- Bispecific antibodies: CS1-NKG2D BsAb
- Chimeric antigen receptor T cells: UCARTCS1, CS1-CAR T

CD38 Directed Therapies

- Naked antibodies: TAK-079
- Immune conjugates: TAK-169, TAK-573, 1053-PE38
- Radio-immune conjugates: Actinium-225-Daratumumab,
- Bispecific antibodies: AMG-424, GBR-1342

Small Molecules

- Exportin-1 inhibitors: selinexor, verdinexor
- CelMods: CC-220, CC-92480
- BCL2 inhibitors: venetoclax, S65487
- MCL1 inhibitors: MIK665, ABV-467, AMG-176, AZD5991
- Proteasome inhibitors: marizomib, oprozomib
- HDAC inhibitors: ACY-1215, bisthianostat
- Bromodomain inhibitors: CPI-0610, RO6870810, ARV825
- MDM2 inhibitors: AMG232, DS3032b, idasanutlin

trial of AMG-420,[217] a short half-life bispecific antibody, was the first proof-of-concept study in relapsed MM patients, showing a 31% ORR (*n* = 42, median 5 prior lines of therapy) for all treated patients but an impressive 70% ORR for those treated with the 400 ug/day, and only a 38% CRS rate (grade 3 = 1%). However, AMG-420 is administered as a continuous infusion over 4 weeks due to its short half-life. An improved half-life product, AMG-701, is now under investigation.[218] Teclistamab, another humanized BCMAx CD3 bispecific antibody, has shown clinical activity in relapsed MM[219, 220] with an ORR of 31% (*n* = 78, median 6 prior lines of therapy), CRS rate of 62% (no ≥ grade 3). A third bispecific monoclonal antibody, CC-93269,[220] reported an ORR of 42% (*n* = 30, median 5 prior lines of therapy) with a CRS rate of 77% (≥ grade 3 = 3%). As these BCMA-directed bispecific monoclonal antibodies get farther along in their clinical development, they may become more attractive, off-the-shelf options for relapsed MM compared to the BCMA CART therapies.

FUTURE DIRECTIONS

Significant advances have occurred in the understanding of the pathobiology of MM, which have translated to development of novel therapeutics. Predictive in vitro and in vivo models have been developed to study growth and survival characteristics of MM cells in the context of the bone marrow microenvironment, but, more important, to preclinically evaluate the efficacy of novel targeted agents. Similarly, there has been an explosion of genomic data covering various genomic correlates including expression profiling, CNA, alternate splicing, miRNA, and now whole-genome and RNA sequencing with mutational analysis of expressed genes as well as noncoding regions. Understanding of mutational landscape, molecular drivers of the disease and patterns, and surrogates of genomic evolution are providing newer clues to disease biology as well as novel therapeutic approaches. Evolving understanding of the epigenomic alterations that affect cell growth, survival, and development of drug resistance is providing clues for novel interventions. For example, there is already an HDAC inhibitor approved for therapy of relapsed myeloma. Moreover, MM cell proliferation is now considered to be dependent on the bromodomain and extraterminal (or "BET") domain family of bromodomain-containing proteins (BRD2, BRD3, and BRD4), and are considered novel therapeutic targets.

Indeed, improved understanding of disease biology has led to new drug development, with 10 new agents approved for myeloma in the last 12 years and over 15 other novel agents being in phase I or II studies. The genomic information is being integrated to develop more accurate risk stratification models and to develop personalized medicine to optimize response while avoiding toxicities. With these advances and use of combinations of agents, there is a significant improvement in the achievement of CR, over 60% to 70% in some studies. This has led to validation of MRD as an important new endpoint in MM with its incorporation into all clinical studies as well as exploration as an ultimate endpoint to achieve cure. Finally, because of these advances, the median survival of patients with MM has increased from 3 years to over 8–10 years, and in a number of individuals, it becomes a chronic disease with curative outcome predicted in a proportion of patients in the near future.

CHAPTER 92

WALDENSTRÖM MACROGLOBULINEMIA/LYMPHOPLASMACYTIC LYMPHOMA

Jorge J. Castillo and Steven P. Treon

Waldenström macroglobulinemia (WM) is a lymphoid neoplasm resulting from the accumulation, predominantly in the bone marrow (BM), of a clonal population of lymphocytes, lymphoplasmacytic cells, and plasma cells, which secrete a monoclonal immunoglobulin (Ig)M.[1] WM corresponds to lymphoplasmacytic lymphoma (LPL) as defined in the World Health Organization classification system.[2] Most cases of LPL are WM; less than 5% of cases secrete IgA, IgG, kappa, lambda, or can be non-secretory LPL.

In 1944, Jan Waldenström, a Swedish physician-scientist, reported in *Acta Medica Scandinavica* three cases of a disease he presciently thought was related to myeloma, but for the absence of skeletal bone involvement and the scarcity of plasma cells in a marrow infiltrated with small lymphocytic cells. He noted an increase in plasma protein concentration, marked increased serum viscosity, exaggerated bleeding, and retinal hemorrhages. In collaboration with a colleague, he showed, using ultracentrifugation and electrophoresis, that the abundant abnormal protein had a molecular weight of approximately 1 million and was not an aggregate of smaller proteins. The disease, which he described with such thoroughness, was later named in his honor.

EPIDEMIOLOGY

The age-adjusted incidence rate of WM in the United States is 3.4 per 1 million among males and 1.7 per 1 million among females. The incidence of WM increases with age.[3,4] The incidence rate is higher among Americans of European descent. Americans of African descent represent approximately 5% of all patients.

Genetic factors play a role in the pathogenesis of WM. Approximately 20% of patients with WM are of Ashkenazi Jewish ethnic background.[5] Familial disease has been reported commonly, including multigenerational clustering of WM and other B-cell lymphoproliferative diseases.[6–9] Approximately 20% of 257 sequential patients with WM presenting to a tertiary referral center had a first-degree relative with either WM or another B-cell disorder.[8] Familial clustering of WM with other immunologic disorders, including hypogammaglobulinemia and hypergammaglobulinemia (particularly polyclonal IgM), autoantibody production (particularly to the thyroid), and manifestation of hyperactive B cells, has also been reported in relatives without WM.[8,9] Increased expression of the *BCL2* gene with enhanced survival has been observed in B cells from familial patients and their family members.[9]

The role of environmental factors is uncertain; however, chronic antigenic stimulation from infections and certain drug or chemical exposures have been considered but have not reached a level of scientific certainty. Hepatitis C virus (HCV) infection was implicated in WM causality in some series, but no association was found in a study of 100 consecutive patients with WM in whom serologic and molecular diagnostic studies for HCV infection were performed.[10–12]

PATHOGENESIS

Nature of the Waldenström Macroglobulinemia Clone

Examination of the B-cell clone(s) found in the BM of patients with WM reveals a range of differentiation, from small lymphocytes with large focal deposits of surface immunoglobulins, to lymphoplasmacytic cells, to mature plasma cells that contain intracytoplasmic IgM (Fig. 92.1).[13] Circulating clonal B cells are often detectable in patients with WM, though lymphocytosis is uncommon.[14,15] WM cells express the monoclonal IgM, and some clonal cells also express surface IgD.[16] The characteristic immunophenotypic profile of WM lymphoplasmacytic cells includes the expression of the pan–B-cell markers CD19, CD20 (including FMC7), CD22, and CD79.[16,17] Expression of CD5, CD10, and CD23 can be present in 10% to 20% of cases, and their presence does not exclude the diagnosis of WM.[18] In addition, multiparameter flow cytometric analysis has also identified CD25 and CD27 as being characteristic of the WM clone, and that a $CD22^{dim}/CD25^{+}/CD27^{+}/IgM^{+}$ population can be observed among clonal B lymphocytes in patients with IgM monoclonal gammopathy of undetermined significance (MGUS) who ultimately progress to WM.[19]

Somatic mutations in immunoglobulin genes are present with increased frequency of nonsynonymous versus silent mutations in complementarity-determining regions, along with somatic hypermutation, thereby supporting a postgerminal center derivation for the WM B-cell clone in most patients.[20,21] A strong preferential use of VH3/JH4 gene families without intraclonal variation, and without evidence for any isotype-switched transcripts, has also been shown.[22,23] Taken together, these data support an IgM^{+} and/or $IgM^{+}IgD^{+}$ memory B-cell origin for most cases of WM.

In contrast to myeloma plasma cells, no recurrent translocations have been described in WM, which can help one distinguish IgM myeloma cases that often exhibit t(11;14) from WM.[24,25] Despite the absence of IgH translocations, recurrent chromosomal abnormalities are present in WM cells. These include deletions in chromosome 6q21–23 in 40% to 60% of patients with WM, with concordant gains in 6p in 41% of patients with 6q deletion.[26–29] In a series of 174 untreated patients with WM, 6q deletions, followed by trisomy 18, 13q deletions, 17p deletions, trisomy 4, and 11q deletions, were observed.[29] Deletion of 6q and trisomy 4 were associated with an adverse prognosis in this series. Because 6q deletions represent the most recurrent cytogenetic finding in WM cases, there has been great interest in identifying the region of minimal deletion and possible target genes within this region. Two putative gene candidates within this region include *TNFAIP3*, a negative regulator of nuclear factor-κB signaling (NFκB), and *PRDM1*, a master regulator of B-cell differentiation.[28,30] The removal of an NFκB-negative regulator is of particular interest because the phosphorylation and translocation of NFκB into the nucleus is a crucial event for WM cell survival.[31] The success of proteasome inhibitor therapy in WM has been postulated to occur because the degradation of negative regulators of NFκB, such as inhibitor of κB (IκB), is blocked.[32,33]

MUTATION IN *MYD88*

A highly recurrent somatic mutation ($\mathit{MYD88}^{L265P}$) was first identified in patients with WM by whole-genome sequencing (WGS) and confirmed by multiple studies through Sanger sequencing and/or allele-specific polymerase chain reaction (PCR) assays.[34–39] $\mathit{MYD88}^{L265P}$ is expressed in 90% to 95% of WM cases when more

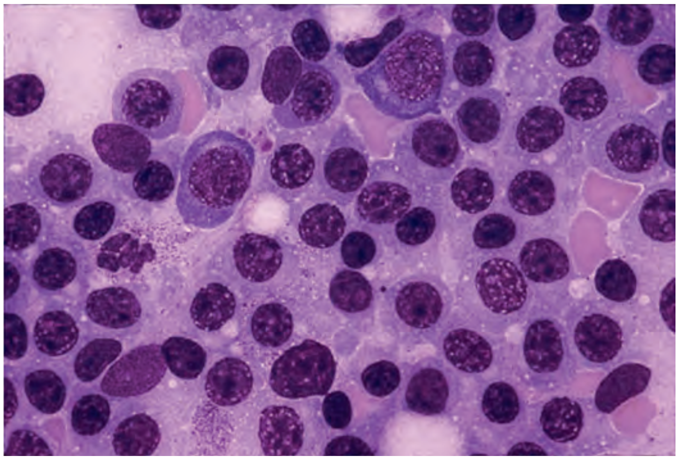

Figure 92.1 MARROW FILM FROM A PATIENT WITH WALDENSTRÖM MACROGLOBULINEMIA. Note infiltrate of mature lymphocytes, lymphoplasmacytic cells, and plasma cells. *(Used with permission from Marvin J. Stone, MD.)*

sensitive allele-specific PCR is employed using both CD19-sorted and unsorted BM cells.[35–39] By comparison, $MYD88^{L265P}$ was absent in myeloma samples, including IgM myeloma, and was expressed in a small subset (6% to 10%) of patients with marginal zone lymphoma, who surprisingly have WM-related features.[35–37,40] By PCR assays, 50% to 80% of patients with IgM MGUS also express $MYD88^{L265P}$, and expression of this mutation was associated with increased risk for malignant progression.[35–37,41] The presence of $MYD88^{L265P}$ in patients with IgM MGUS suggests a role for this mutation as an early oncogenic driver, and other mutations and/or copy number alterations leading to abnormal gene expression are likely to promote disease progression.[28]

The impact of $MYD88^{L265P}$ to growth and survival signaling in WM cells has been addressed in several studies (Fig. 92.2). Knockdown of *MYD88* decreased survival of $MYD88^{L265P}$-expressing WM cells, whereas survival was enhanced by knock-in of $MYD88^{L265P}$ versus wild-type (WT) *MYD88*.[42] The discovery of a mutation in MYD88 is of significance, given its role as an adaptor molecule in Toll-like receptor (TLR) and interleukin-1 receptor (IL-1R) signaling.[43] All TLRs except for TLR3 use MYD88 to facilitate their signaling. Following TLR or IL-1R stimulation, MYD88 is recruited to the activated receptor complex as a homodimer, which then complexes with interleukin receptor-associated kinase 4 (IRAK4) and activates IRAK1 and IRAK2.[44–46] Tumor necrosis factor receptor-associated factor 6 is then activated by IRAK1, leading to NFκB activation via IκBα phosphorylation.[47] Use of inhibitors of the MYD88 pathway led to decreased IRAK1 and IκBα phosphorylation, as well as to survival of $MYD88^{L265P}$-expressing WM cells. These observations are of particular relevance to WM because NFκB signaling is important for WM growth and survival.[48] Bruton's tyrosine kinase (BTK) is also activated by $MYD88^{L265P}$.[42] Activated BTK coimmunoprecipitates with MYD88, which could be abrogated by use of a BTK inhibitor,

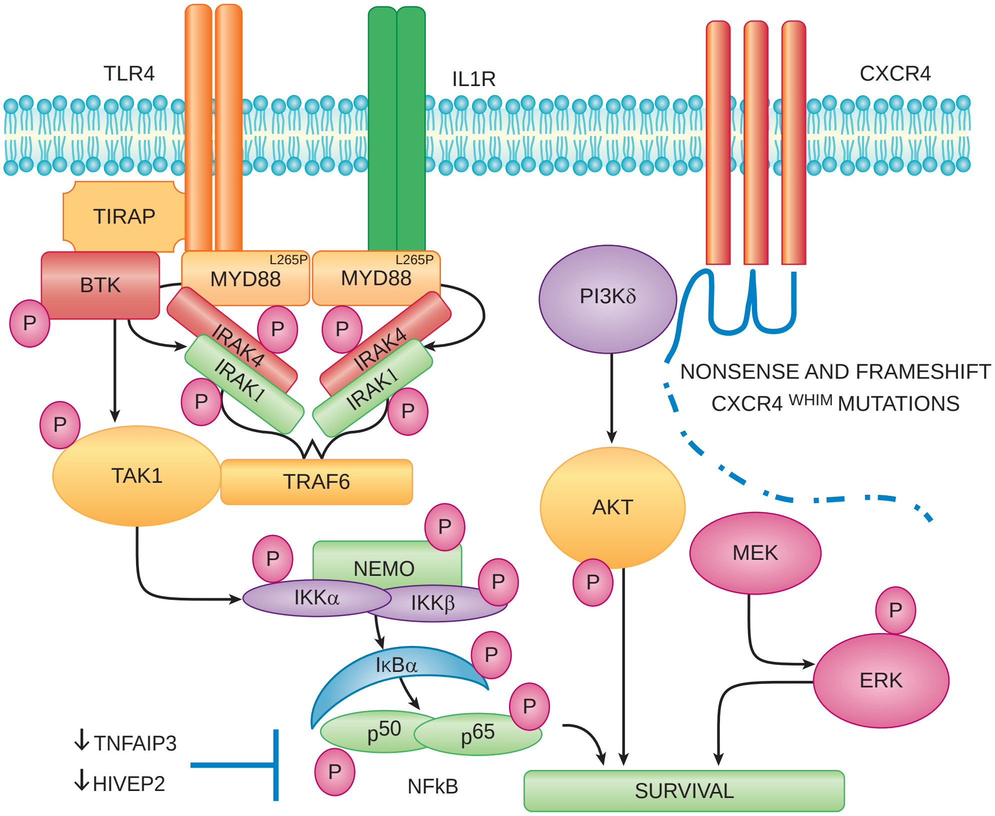

Figure 92.2 *$MYD88^{L265P}$* AND *$CXCR4^{WHIM}$* MUTATIONS ARE HIGHLY PREVALENT IN PATIENTS WITH WALDENSTRÖM MACROGLOBULINEMIA AND TRIGGER TRANSCRIPTIONAL FACTORS THAT INCLUDE NUCLEAR FACTOR-κB (NFκB), AKT, AND EXTRACELLULAR SIGNAL-REGULATED KINASE (ERK) THAT SUPPORT THE GROWTH AND SURVIVAL OF LYMPHOPLASMACYTIC CELLS. *BTK*, Bruton's tyrosine kinase; *CXCR4*, C-X-C chemokine receptor type 4; *HIVEP2*, human immunodeficiency virus type I enhancer binding protein 2; *IKBα*, nuclear factor of κ light polypeptide gene enhancer in B cells inhibitor α; *IKK*, inhibitor of nuclear factor-κB kinase; *IL1R*, interleukin-1 receptor; *IRAK*, interleukin receptor-associated kinase; *MEK*, mitogen-activated protein kinase kinase; *NEMO*, nuclear factor-κB essential modulator; *NFκB*, nuclear factor-κB; *PI3Kδ*, phosphoinositide 3-kinase δ; *TAK1*, transforming growth factor β-activated kinase 1; *TIRAP*, Toll-interleukin 1 receptor domain-containing adaptor protein; *TLR4*, Toll-like receptor 4; *TNFAIP3*, tumor necrosis factor α-induced protein 3; *TRAF6*, tumor necrosis factor α receptor-associated factor 6; *WHIM*, warts, hypogammaglobulinemia, infections, and myelokathexis syndrome.

and overexpression of *MYD88*^{L265P} but not WT *MYD88* triggers BTK activation. Knockdown of *MYD88* by lentiviral transfection or use of a MYD88 homodimerization inhibitor also abrogated BTK activation in *MYD88*^{L265P}-mutated WM cells.

CXCR4 WHIM MUTATIONS

The second most common somatic mutation after *MYD88*^{L265P} revealed by WGS was found in the C-terminus of the C-X-C chemokine receptor type 4 (CXCR4) receptor. These mutations are present in 30% to 35% of patients with WM, and they impact serine phosphorylation sites that regulate CXCR4 signaling by its only known ligand, SDF-1α (CXCL12).[28,49–51] The location of somatic mutations found in the C-terminus of *CXCR4* in WM are similar to those observed in the germline of patients with WHIM (warts, hypogammaglobulinemia, infections, and myelokathexis, retention of neutrophils within the marrow) syndrome, a congenital immunodeficiency disorder characterized by chronic noncyclic neutropenia.[52] Patients with WHIM syndrome exhibit impaired CXCR4 receptor internalization following SDF-1α stimulation, which results in persistent CXCR4 activation and myelokathexis.[53]

In patients with WM, two classes of *CXCR4* mutations occur in the C-terminus. These include nonsense *(CXCR4*^{NS}*)* mutations that truncate the distal 15– to 20–amino acid region and frameshift *(CXCR4*^{FS}*)* mutations that comprise a region of up to 40 amino acids in the C-terminal domain.[28,49] Nonsense and frameshift mutations are almost equally divided among patients with WM with *CXCR4* somatic mutations, and over 30 different types of *CXCR4* mutations have been identified in patients with WM.[28,49] Preclinical studies with WM cells engineered to express nonsense and frameshift *CXCR4*-mutated receptors have shown enhanced and sustained AKT and extracellular signal-regulated kinase signaling following SDF-1α relative to wild type CXCR4 (*CXCR4*^{WT}) (see Fig. 92.2), as well as increased cell migration, adhesion, growth, and survival, and also drug resistance of WM cells.[50,54,55]

Other Somatic Events

Many copy number alterations have been revealed in patients with WM that impact growth and survival pathways. Frequent loss of *HIVEP2* (80%) and *TNAIP3* (50%) genes that are negative regulators of NFκB expression (see Fig. 92.2), as well as *LYN* (70%) and *IBTK* (40%) that modulate B-cell receptor signaling have been revealed by WGS.[28] WGS has also revealed common defects in chromatin remodeling, with somatic mutations in ARID1A present in 17% and loss of *ARID1B* in 70% of patients with WM. Both *ARID1A* and *ARID1B* are members of the SWI/SNF family of proteins, and are thought to exert their effects via p53 and cyclin-dependent kinase inhibitor 1A regulation. TP53 is mutated in 7% of sequenced WM genomes, whereas *PRDM2* and *TOP1* that participate in TP53-related signaling are deleted in 80% and 60% of patients with WM, respectively.[28] Taken together, somatic events that contribute to impaired DNA damage response are also common in WM.

IMPACT OF WM GENOMICS ON CLINICAL PRESENTATION

The importance of *MYD88* and *CXCR4* mutations in the clinical presentation of patients with WM has been established. Significantly higher BM involvement, serum IgM levels, hyperviscosity syndrome, and acquired von Willebrand disease were observed in the patients with *MYD88*^{L265P}*CXCR4*^{NS} mutations.[49,56] Patients with *MYD88*^{L265P}*CXCR4*^{FS} or *MYD88*^{L265P}*CXCR4*^{WT} had intermediate BM and serum IgM levels; those with *MYD88*^{WT}*CXCR4*^{WT} showed the lowest BM disease burden. Fewer patients with *MYD88*^{L265P} and *CXCR4*$^{FS\ or\ NS}$ than with *MYD88*^{L265P}*CXCR4*^{WT} presented with adenopathy, further delineating differences in disease tropism based on *CXCR4* status. Despite the more aggressive presentation associated with *CXCR4*^{NS} genotype, risk of death was not impacted by *CXCR4* mutation status. Risk of death and histological transformation to more aggressive lymphoma were found to be higher in patients with the *MYD88*^{WT} versus the *MYD88*^{L265P} genotype.[49,57]

MARROW MICROENVIRONMENT

In patients with WM, increased numbers of mast cells are found in the BM, where they are usually admixed with tumor cell aggregates (Fig. 92.3).[13,17,58] The role of mast cells in WM has been investigated in one study in which coculture of primary autologous or mast cell lines with WM lymphoplasmacytic cells resulted in dose-dependent WM cell proliferation and/or tumor colony formation through CD40 ligand (CD40L) signaling.[58] WM cells release soluble CD27 (sCD27), which may be triggered by cleavage of membrane bound CD27 by matrix metalloproteinase 8.[59] sCD27 levels are elevated in the serum of patients with WM and follow disease burden in mice engrafted with WM cells, as well as in patients with WM.[60] sCD27 triggers the upregulation of CD40L as well as a proliferation-inducing ligand on mast cells derived from patients with WM, and mast cell lines through its receptor CD70. Modeling in mice treated with a CD70-blocking antibody shows inhibition of tumor cell growth, suggesting that WM cells require a microenvironmental support system for their growth and survival.[61] High levels of CXCR4 and very late antigen-4 (VLA-4) are expressed by WM cells.[60] In blocking experiment studies, CXCR4 was shown to support migration of WM cells, whereas VLA-4 contributed to adhesion of WM cells to BM stromal cells.[60]

CLINICAL FEATURES

Table 92.1 provides the clinical and laboratory features at the time of diagnosis of patients with WM in one large institutional study.[15] Unlike most indolent lymphomas, splenomegaly and lymphadenopathy are uncommon (≤15%). Purpura is frequently associated with

cryoglobulinemia and in rare circumstances with light-chain (AL) amyloidosis. Hemorrhagic and neuropathic manifestations are multifactorial (see IgM-Related Neuropathy section below). The morbidity associated with WM is caused by the co-occurrence of two main components: tissue infiltration by neoplastic cells and, importantly, the physicochemical and immunologic properties of the monoclonal IgM. As shown in Table 92.2, the monoclonal IgM can produce clinical manifestations through several different mechanisms related to its physicochemical properties, nonspecific interactions with other proteins, antibody activity, and tendency to deposit in tissues.[62–64]

MORBIDITY MEDIATED BY THE EFFECTS OF IMMUNOGLOBULIN M

Hyperviscosity Syndrome

The increased plasma IgM levels lead to increased blood hyperviscosity and complications.[65] The mechanisms behind the marked increase in the resistance to blood flow and the resulting impaired transit through the microcirculatory system are complex.[65–68] The main determinants are (1) a high concentration of monoclonal IgMs, which may form aggregates and may bind water through their carbohydrate component; and (2) the interaction of IgMs with blood cells. Monoclonal IgM increases red cell aggregation (rouleau formation) and red cell internal viscosity while reducing red cell deformability. The presence of cryoglobulins contributes to increasing blood viscosity, as well as the tendency to induce erythrocyte aggregation. Serum viscosity is negligible up to an IgM concentration up to 30 g/L, then increases sharply at higher levels, with a median time to symptomatic hyperviscosity of 3 months when IgM levels surpass 60 g/L.[69] Increased plasma viscosity may also contribute to inappropriately low erythropoietin production, which is the major reason for anemia in these patients.[68] Renal synthesis of erythropoietin is inversely correlated with plasma viscosity. Clinical manifestations are related to circulatory disturbances that can best be appreciated by ophthalmoscopy, which shows distended and tortuous retinal veins, hemorrhages, and papilledema (Fig. 92.4).[70] Symptoms usually occur when the monoclonal IgM concentration exceeds 50 g/L or when serum viscosity is greater than 4.0 centipoises (cp), but there is individual variability, with some patients showing no evidence of hyperviscosity even at 10 cp.[65] The most common symptoms are oronasal mucosal bleeding, visual disturbances because of retinal bleeding, and dizziness that rarely may lead to stupor or coma. Heart failure can be aggravated, particularly in the elderly, owing to increased blood viscosity, expanded plasma volume, and anemia. Inappropriate red cell transfusions can exacerbate hyperviscosity and may precipitate cardiac failure.

Cryoglobulinemia

The monoclonal IgM can behave as a type I cryoglobulin in up to 20% of patients, and it leads to no symptoms in most cases.[15,64,71,72] Cryoprecipitation is dependent mainly on the concentration of monoclonal IgM; for this reason, plasmapheresis or plasma exchange

TABLE 92.2 **Physicochemical and Immunologic Properties of the Monoclonal Immunoglobulin M Protein in Waldenström Macroglobulinemia**

Properties of IgM Monoclonal Protein	Diagnostic Condition	Clinical Manifestations
Pentameric structure	Hyperviscosity	Headaches, blurred vision, epistaxis, retinal hemorrhages, leg cramps, impaired mentation, intracranial hemorrhage
Precipitation on cooling	Cryoglobulinemia (type I)	Raynaud phenomenon, acrocyanosis, ulcers, purpura, cold urticaria
Autoantibody activity to myelin-associated glycoprotein, ganglioside M_1, sulfatide moieties on peripheral nerve sheaths	Peripheral neuropathies	Sensorimotor neuropathies, painful neuropathies, ataxic gait, bilateral foot drop
Autoantibody activity to IgG	Cryoglobulinemia (type II)	Purpura, arthralgia, renal failure, sensorimotor neuropathies
Autoantibody activity to red blood cell antigens	Cold agglutinins	Hemolytic anemia, Raynaud phenomenon, acrocyanosis, livedo reticularis
Tissue deposition as amorphous aggregates	Organ dysfunction	Skin: bullous skin disease, papules, Schnitzler syndrome Gastrointestinal: diarrhea, malabsorption, bleeding Kidney: proteinuria, renal failure (light-chain component)
Tissue deposition as amyloid fibrils (light-chain component most commonly)	Organ dysfunction	Fatigue, weight loss, edema, hepatomegaly, macroglossia, organ dysfunction of involved organs (heart, kidney, liver, peripheral sensory and autonomic nerves)

IgM, Immunoglobulin M.

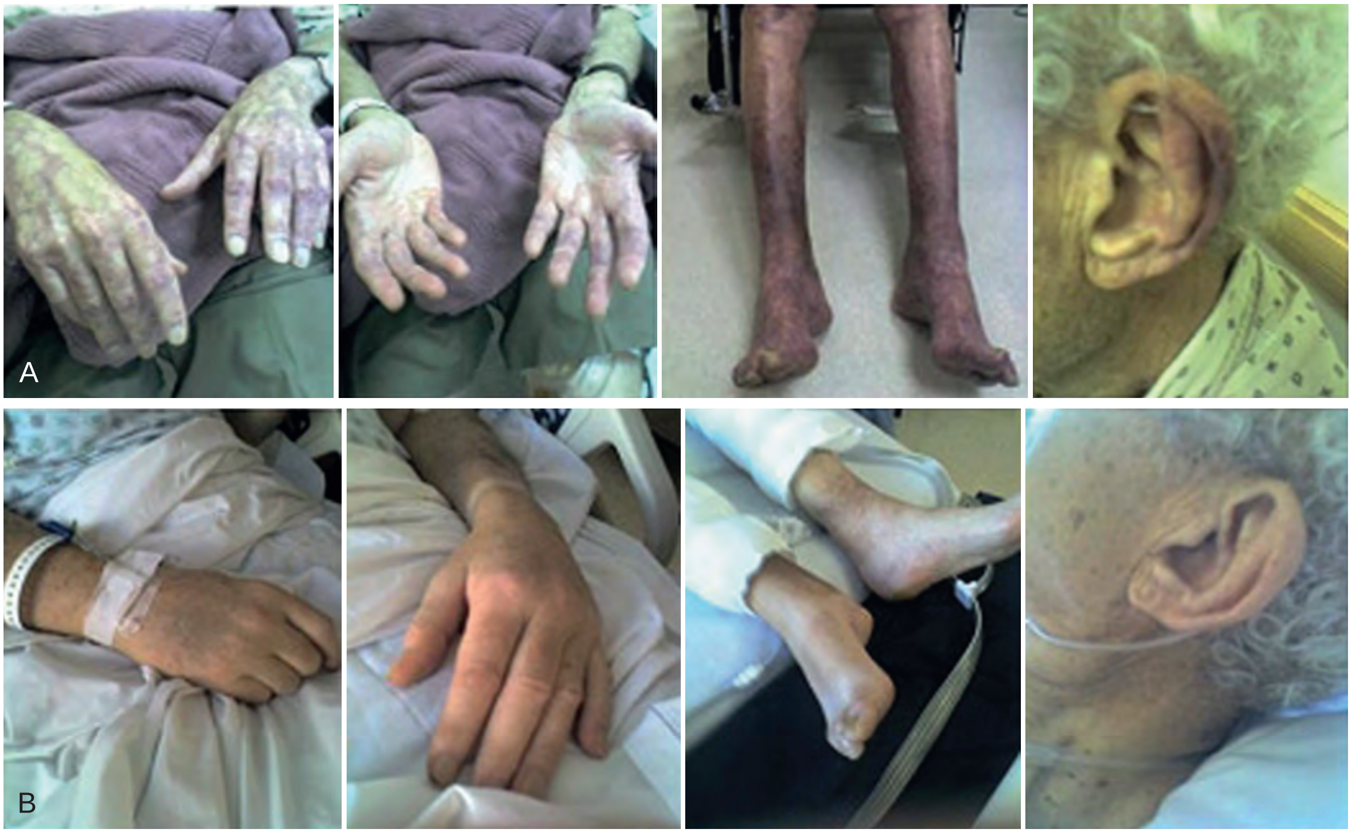

Figure 92.4 Cryoglobulinemia manifesting with severe acrocyanosis in a patient with Waldenström macroglobulinemia (A) before and (B) following warming and plasmapheresis.

is commonly effective in this condition. Symptoms result from impaired blood flow in small vessels and include Raynaud's phenomenon; acrocyanosis; necrosis of the regions most exposed to cold, such as the tips of the nose, ears, fingers, and toes (Fig. 92.5); malleolar ulcers; purpura; and cold urticaria. Renal manifestations are infrequent. Mixed cryoglobulins (type II) consisting of IgM-IgG complexes may be associated with HCV infection.[73]

Autoantibody Activity

Monoclonal IgM may exert its pathogenic effects through specific recognition of autologous antigens, the most notable being nerve constituents, immunoglobulin determinants, and red blood cell antigens.

Immunoglobulin M–Related Neuropathy

IgM-related peripheral neuropathy is common in patients with WM, with estimated prevalence rates of 5% to 40%.[73–75] Approximately 8% of idiopathic neuropathies are associated with a monoclonal gammopathy, with a preponderance of IgM (60%), followed by IgG (30%) and IgA (10%).[76,77] The nerve damage is mediated by diverse pathogenetic mechanisms: (1) IgM antibody activity toward nerve constituents causing demyelinating polyneuropathies; (2) endoneurial granulofibrillar deposits of IgM without antibody activity, associated with axonal polyneuropathy; (3) occasionally by tubular deposits in the endoneurium associated with IgM cryoglobulin; and, rarely, (4) amyloid deposits or neoplastic cell infiltration of nerve structures.[75,78]

Half of the patients with IgM neuropathy have a distinctive clinical syndrome that is associated with antibodies against a minor 100 kDa glycoprotein component of nerve known as the *myelin-associated glycoprotein* (MAG). Anti-MAG antibodies are generally monoclonal IgMκ and usually also exhibit reactivity with other glycoproteins or glycolipids that share antigenic determinants with MAG.[79–81] The anti–MAG-related neuropathy is typically distal and symmetrical, affecting both motor and sensory functions; it is slowly progressive with a long period of stability.[74,82] Most patients present with sensory complaints (paresthesias, aching discomfort, dysesthesias, or lancinating pains); imbalance and gait ataxia, owing to lack proprioception; and muscle atrophy in advanced stage. Patients with predominantly demyelinating sensory neuropathy in association with monoclonal IgM to gangliosides with disialosyl moieties, such as GD1b, GD3, GD2, GT1b, and GQ1b, have also been reported.[83,84] Anti-GD1b and anti-GQ1b antibodies were associated with sensory ataxic neuropathy. These antiganglioside monoclonal IgMs present core clinical features of chronic ataxic neuropathy, sometimes associated with ophthalmoplegia and/or red blood cell cold agglutinating activity. The disialosyl epitope is also present on red blood cell glycophorins, thereby accounting for the red cell cold agglutinin activity of anti-Pr2 specificity.[85,86] Monoclonal IgM proteins that bind to gangliosides with a terminal trisaccharide moiety, including ganglioside M_2 and GalNac-GD1A, are associated with chronic demyelinating neuropathy and severe sensory ataxia, unresponsive to glucocorticoids.[87] Antiganglioside IgM proteins may also cross-react with lipopolysaccharides of *Campylobacter jejuni*, an infection known to precipitate the Miller Fisher syndrome, a variant of Guillain-Barré syndrome.[85] Thus, molecular mimicry may play a role in this condition. Anti-sulfatide monoclonal IgM proteins, associated with sensory-sensorimotor neuropathy, have been detected in 5% of patients with IgM monoclonal gammopathy and neuropathy.[88] Motor neuron disease has been reported in patients with WM and monoclonal IgM with anti-GM_1 and sulfoglucuronyl paragloboside activity.[89] Polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes (the POEMS syndrome) are rare in patients with WM.[90]

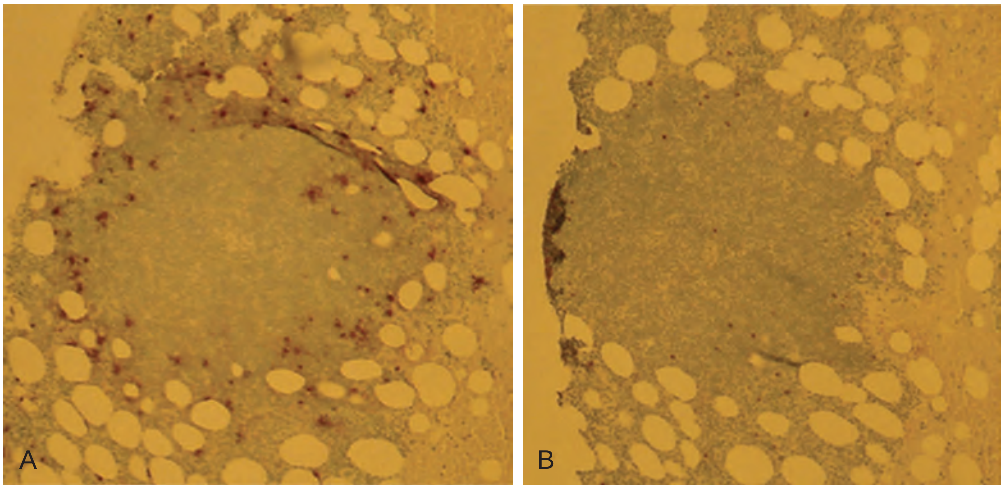

Figure 92.5 MARROW CLOT SECTION. (A) Tryptase-staining mast cells surrounding a nodule of lymphoplasmacytic cells in a patient with Waldenström macroglobulinemia. (B) Mast cells in the same section exhibit strong CD40 ligand signaling, which has been shown to support (at least in part) the growth and survival of lymphoplasmacytic cells.

Cold Agglutinin Hemolytic Anemia

Monoclonal IgMs may have cold agglutinin activity; they recognize specific red cell antigens at temperatures below 37°C, producing a chronic hemolytic anemia (see Chapter 47). This disorder occurs in less than 10% of patients with WM and is associated with cold agglutinin titers greater than 1:1000 in most cases.[91] The monoclonal component is usually an IgMκ and reacts most commonly with red cell I/i antigens, resulting in complement fixation and activation.[92,93] Mild to moderate chronic hemolytic anemia can be exacerbated after cold exposure. Hemoglobin levels usually remain above 70 g/L. The hemolysis is usually extravascular, mediated by the removal of C3b opsonized red cells by the mononuclear phagocytes, primarily in the liver. Intravascular hemolysis from complement destruction of red blood cell membrane is infrequent. The agglutination of red cells in the skin circulation also causes Raynaud syndrome, acrocyanosis, and livedo reticularis. Macroglobulins with the properties of both cryoglobulins and cold agglutinins with anti-Pr blood group specificity can occur. These properties may have as a common basis the binding of the sialic acid–containing carbohydrate present on red blood cell glycophorins, which involve the Pr blood group and Ig molecules. Several other macroglobulins with antibody activity toward autologous antigens (e.g., phospholipids, tissue and plasma proteins), and foreign ligands have also been described.

Immunoglobulin M Tissue Deposition

The monoclonal IgM can be deposited into several tissues as amorphous aggregates. Linear deposition of monoclonal IgM along the skin basement membrane is associated with bullous skin disease.[94] Amorphous IgM deposits in the dermis result in IgM storage papules on the extensor surface of the extremities, referred to as *macroglobulinemia cutis*.[95] Deposition of monoclonal IgM in the lamina propria and/or submucosa of the intestine may be associated with diarrhea, malabsorption, and gastrointestinal bleeding.[96,97] Kidney involvement is less common and less severe in WM than in myeloma, probably because the amount of light chain that is excreted in the urine is generally less in WM than in myeloma and because of the absence of contributing factors, such as hypercalcemia. Urinary cast nephropathy, however, has been reported in WM.[98] On the other hand, the IgM macromolecule is more susceptible to being trapped in the glomerular loops, where ultrafiltration presumably contributes to its precipitation, forming subendothelial deposits of aggregated IgM proteins that occlude the glomerular capillaries.[99] Mild and reversible proteinuria may result, and most patients are asymptomatic. The deposition of monoclonal light chain as fibrillar amyloid deposits (AL amyloidosis) (Chapter 93) is uncommon in patients with WM.[100] The clinical manifestations and prognosis are similar to those of other patients with AL amyloidosis, with involvement occurring in the heart (44%), kidneys (32%), liver (14%), lungs (10%), peripheral or autonomic nerves (38%), and soft tissues (18%). The incidence of cardiac and pulmonary involvement is higher in patients with monoclonal IgM than in those with other immunoglobulin isotypes. The association of WM with reactive or ATTR amyloidosis has been documented rarely.[101–103] Simultaneous occurrence of fibrillary glomerulopathy, characterized by glomerular deposits of wide noncongophilic fibrils and amyloid deposits, has been described.[104]

Manifestations Related to Tissue Infiltration by Neoplastic Cells

Tissue infiltration by neoplastic cells is uncommon but can involve various organs and tissues, including the liver, spleen, lymph nodes, lungs, gastrointestinal tract, kidneys, skin, eyes, and central nervous system.

Lung

Pulmonary involvement in the form of masses, nodules, diffuse infiltrate, or pleural effusions is uncommon; the overall incidence of pulmonary and pleural findings is approximately 4%.[105–107] Cough is the most common presenting symptom, followed by dyspnea and chest pain. Chest radiographic findings include parenchymal infiltrates, confluent masses, and effusions.

Gastrointestinal Tract

Malabsorption, diarrhea, bleeding, or obstruction may indicate involvement of the gastrointestinal tract at the level of the stomach, duodenum, or small intestine.[108–111]

Renal System

In contrast to myeloma, infiltration of the kidney interstitium with lymphoplasmacytoid cell can occur in WM, and renal or perirenal masses are not uncommon.[112,113]

Skin

The skin can be the site of dense lymphoplasmacytic infiltrates, similar to those seen in the liver, spleen, and lymph nodes, forming cutaneous plaques and, rarely, nodules.[114] Chronic urticaria and IgM gammopathy are the two cardinal features of the Schnitzler syndrome, which is not usually associated initially with clinical features of WM, although evolution to WM is not uncommon.[115] Thus close follow-ups of such patients are important.

Joints

Invasion of articular and periarticular structures by WM malignant cells is rarely reported.[116]

Eye

The neoplastic cells can infiltrate the periorbital structures, lacrimal gland, and retro-orbital lymphoid tissues, resulting in ocular nerve palsies.[117,118]

Central Nervous System

Direct infiltration of the central nervous system by monoclonal lymphoplasmacytic cells as infiltrates or as tumors constitutes the rarely observed Bing-Neel syndrome, characterized clinically by confusion, memory loss, disorientation, and sensory or motor dysfunction.[120,121]

LABORATORY FINDINGS

Blood Abnormalities

Anemia is the most common finding in patients with symptomatic WM and is caused by a combination of factors: decrease in red cell survival, impaired erythropoiesis, moderate plasma volume expansion, hepcidin production leading to an iron reuse defect, and blood loss from the gastrointestinal tract.[15,121,122] Blood films are usually normocytic and normochromic, and rouleau formation is often pronounced. Mean red cell volume may be elevated spuriously owing to erythrocyte aggregation. In addition, the hemoglobin estimate can be inaccurate (i.e., falsely high) because of interaction between the monoclonal protein and the diluent used in some automated analyzers.[118] Leukocyte and platelet counts are usually within their reference ranges at presentation, although patients may occasionally present with severe thrombocytopenia. Monoclonal B lymphocytes expressing surface IgM and late-differentiation B-cell markers are uncommonly detected in blood by flow cytometry. A raised erythrocyte sedimentation rate is almost always present and may be the first clue to the presence of macroglobulinemia. The clotting abnormality detected most frequently is the prolongation of thrombin time. AL amyloidosis (Chapter 93) should be suspected in all patients with nephrotic syndrome, cardiomyopathy, hepatomegaly, or peripheral neuropathy. Diagnosis requires the demonstration of green birefringence under polarized light of amyloid deposits stained with Congo red with further confirmation of light chain amyloidosis by mass spectrometry.[123]

MARROW FINDINGS

Central to the diagnosis of WM is the demonstration, by trephine biopsy, of marrow infiltration by a lymphoplasmacytic cell population characterized by small lymphocytes with evidence of plasmacytoid and plasma cell maturation (see Fig. 92.1).[1,13] The pattern of marrow infiltration may be diffuse, interstitial, or nodular, usually with an intertrabecular pattern of infiltration. A solely paratrabecular pattern of infiltration is unusual and should raise the possibility of follicular lymphoma.[1] The marrow cell immunophenotype should be confirmed by flow cytometry and/or immunohistochemistry. The cell immunoprofile sIgM$^+$CD19$^+$CD20$^+$CD22$^+$CD79$^+$ is characteristic of WM.[13,124,125] Up to 20% of cases may express either CD5, CD10, or CD23.[18] In these cases, chronic lymphocytic leukemia and mantle cell lymphoma should be excluded. “Intranuclear” periodic acid-Schiff–positive inclusions (Dutcher-Fahey bodies)[126] consisting of IgM deposits in the perinuclear space, and sometimes in intranuclear vacuoles, may be seen occasionally in lymphoid cells. An increased number of mast cells, usually in association with the lymphoid aggregates, is commonly found, and their presence may help in differentiating WM from other B-cell lymphomas (see Fig. 92.3).[13] *MYD88*^{L265P} testing of BM samples has been incorporated into many clinical laboratories and may help in clarifying the diagnosis of WM from other IgM-secreting entities, such as IgM multiple myeloma or marginal zone lymphoma.[34–38] The use of peripheral blood B cells may also permit determination of *MYD88*^{L265P} status by allele-specific PCR assays, particularly in untreated patients with WM.

IMMUNOLOGIC ABNORMALITIES

High-resolution electrophoresis combined with immunofixation of serum and urine is recommended for identification and characterization of the IgM monoclonal protein. The light chain of the monoclonal IgM is κ in 75% to 80% of patients. More than one M component may be present. The concentration of the serum monoclonal protein is very variable, but in most cases, it lies within the range of 15 to 45 g/L. Densitometry should be adopted to determine IgM levels for serial evaluations because nephelometry is unreliable and shows large laboratory variation. The presence of cold agglutinins or cryoglobulins may affect determination of IgM levels, and, therefore, testing for cold agglutinins and cryoglobulins should be performed at diagnosis. If present, subsequent serum samples should be analyzed at 37°C for determination of serum monoclonal IgM level. Although Bence Jones proteinuria is frequently present, it exceeds 1 g/24 h in only 3% of cases. Whereas IgM levels are elevated in patients with WM, IgA and IgG levels are most often depressed and might not recover after successful treatment.[127]

SERUM VISCOSITY

Because of their large size (molecular weight almost 1 million), most IgM molecules are retained within the intravascular compartment and can exert an undue effect on serum viscosity.[63] Serum viscosity can be measured if the patient has signs or symptoms of hyperviscosity syndrome, though levels are often slow to be reported and erratic owing to a lack of standardization in most clinical laboratories.[15] As such, serum IgM levels may be more expedient and relied upon. Patients typically become symptomatic at serum viscosity levels of 4.0 cp and above, which correspond to serum IgM levels above 6,000 mg/dL.[128,129] Patients may be symptomatic at lower serum viscosity and IgM levels, and in these patients cryoglobulins may be present. Recurring nosebleeds, headaches, and visual disturbances are common symptoms in patients with symptomatic hyperviscosity.[15] Funduscopy is an important indicator of clinically relevant hyperviscosity. Among the first clinical signs of hyperviscosity are the appearance of peripheral and midperipheral dot- and blot-like hemorrhages in the retina, which are best appreciated with indirect ophthalmoscopy and scleral depression.[70] In more severe cases of hyperviscosity, dot, blot, and flame-shaped hemorrhages can appear in the macular area along with markedly dilated and tortuous veins with focal constrictions resulting in “venous sausaging,” as well as papilledema (see Fig. 92.4).

IMAGING

Magnetic resonance imaging (MRI) of the spine in conjunction with computed tomography (CT) of the abdomen and pelvis are useful in evaluating disease status.[130] Marrow involvement can be documented by MRI studies of the spine in more than 90% of patients; CT of the abdomen and pelvis demonstrates enlarged nodes in approximately 20% of patients with WM at diagnosis, but this proportion may be higher at relapse.[130]

LYMPH NODE BIOPSY

Lymph node biopsy may show preserved architecture or replacement by infiltration of neoplastic cells with lymphoplasmacytoid, lymphoplasmacytic, or polymorphous cytologic patterns.

TREATMENT

Initiating Treatment

As part of the Second International Workshop on Waldenström Macroglobulinemia, a consensus panel was organized to recommend criteria for the initiation of therapy in patients with WM.[131] The panel recommended that initiation of therapy should not be based on the IgM level per se, because this may not correlate with the clinical manifestations of WM. The consensus panel did, however, agree that initiation of therapy is appropriate for patients with constitutional symptoms, such as recurrent fever, night sweats, fatigue as a consequence of anemia, or weight loss. Progressive symptomatic lymphadenopathy and/or splenomegaly provide additional reasons to begin therapy. Anemia with a hemoglobin value ≤10 g/dL or a platelet count ≤100 × 10^9/L owing to marrow infiltration also justifies treatment. Certain complications, such as hyperviscosity syndrome, symptomatic sensorimotor peripheral neuropathy, systemic amyloidosis, renal insufficiency, or symptomatic cryoglobulinemia, may also be indications for therapy.[15,131,132]

Initial Therapy

The International Workshops on Waldenström Macroglobulinemia have formulated consensus recommendations for both initial therapy and therapy for refractory disease based on the best available evidence. The most recent recommendations emerged from the Tenth International Workshop on Waldenström Macroglobulinemia.[133] Individual patient considerations, including the presence of cytopenias, need for more rapid disease control, age, and candidacy for autologous transplant therapy, should be taken into account in making the choice of the drugs to use. For patients who are candidates for autologous stem cell transplant (SCT), which typically is reserved for those patients younger than 70 years of age, the panel recommended that exposure to alkylating agents or nucleoside analogues should be limited. The use of nucleoside analogues should be approached cautiously in patients with WM because there appears to be an increased risk for the development of disease transformation as well as myelodysplasia and acute myeloid leukemia. For patients who present with symptomatic hyperviscosity, cryoglobulinemia or cold agglutinin anemia, rapid control of the disease can be achieved with plasmapheresis. However, plasmapheresis should be considered a temporary control measure and should be immediately followed by definitive therapy. A proposed algorithm for initial treatment selection based on genomic profile in WM patients is shown in Fig. 92.6.[134]

Oral Alkylating Agents

Oral alkylating drugs, alone and in combination therapy with glucocorticoids, have been evaluated extensively in the treatment of WM. Chlorambucil has been administered on both a continuous (i.e., daily dose schedule) and an intermittent schedule. In a prospective, randomized study, a significant difference in the overall response rate (ORR) between these schedules was not observed,[135] although the median

Benda-R, PI-based regimen
Alternative: DRC, BTK-I + rituximab

Figure 92.6 GENOMIC-BASED TREATMENT ALGORITHM FOR SYMPTOMATIC TREATMENT-NAÏVE PATIENTS WITH WALDENSTRÖM MACROGLOBULINEMIA (WM). *Benda-R*, bendamustine and rituximab; *BTK-I*, Bruton tyrosine kinase inhibitor; *CAGG*, cold agglutinin disease; *CRYOS*, cryoglobulins; *DRC*, dexamethasone, rituximab, cyclophosphamide; *HV*, hyperviscosity; *PI*, proteasome inhibitor; *PN*, progressive neuropathy. *(From Treon SP, Xu L, Guerrera ML, et al. Genomic landscape of Waldenström macroglobulinemia and its impact on treatment strategies. J Clin Oncol. 2020;38(11):1198–1208.)*

response duration was greater for patients receiving intermittent- versus continuous-dose chlorambucil (46 vs. 26 months). Despite the favorable median response duration in this study for use of the intermittent schedule, differences in the median overall survival were not observed. Moreover, an increased incidence of myelodysplasia and acute myeloid leukemia was observed with the intermittent (3 of 22 patients) versus the continuous (0 of 24 patients) chlorambucil schedule prompted the preference for use of continuous chlorambucil dosing. The use of glucocorticoids in combination with alkylating agent therapy has also been explored, resulting in a major response (i.e., reduction of IgM by more than 50%) in 72% of patients.[136] Alkylating agent regimens employing melphalan and cyclophosphamide in combination with glucocorticoids have also been examined.[137,138] This approach produced slightly higher ORRs and response durations, although the benefit of these more complex regimens over chlorambucil remains to be demonstrated. Pretreatment factors associated with shorter survival of patients receiving single-agent chlorambucil were age greater than 60 years, male sex, hemoglobin less than 10 g/dL, leukocytes less than 4×10^9/L, and platelets less than 150×10^9/L. Organomegaly, signs of hyperviscosity, renal failure, monoclonal IgM level, blood lymphocytosis, and percentage of marrow lymphoid cells were not significantly correlated with survival.[139] Additional factors to be taken into account in considering alkylating agent therapy for patients with WM include necessity for more rapid disease control, given the slow response, as well as consideration for preserving stem cells in patients who are candidates for autologous SCT. A large, randomized study showed an inferior response rate and time to progression in patients with WM receiving chlorambucil versus fludarabine, as well as a higher incidence of secondary malignancies in the former. Neutropenia was more pronounced, however, in those patients on fludarabine.[140]

Nucleoside Analogue Therapy

Cladribine has resulted in major responses in 40% to 90% of WM patients who received primary therapy, whereas in the previously treated patients, responses have ranged from 38% to 54%.[141–147] Median time to achievement of response in responding patients following cladribine ranged from 1.2 to 5 months. The ORR with daily infusion of fludarabine, administered mainly on 5-day schedules, in previously untreated and treated patients ranged from 38% to 100% and from 30% to 40%, respectively,[148–153] similar to the responses to cladribine. Median time to achievement of a response with fludarabine (3 to 6 months) was also similar to cladribine. In general, response rates and durations of responses have been greater for patients receiving nucleoside analogues as initial therapy, although no difference in the ORR was reported in several studies in which both untreated and previously treated patients were enrolled.

Myelosuppression commonly occurs following prolonged exposure to either of the nucleoside analogues. A sustained decrease in both $CD4^+$ and $CD8^+$ T lymphocytes, measured 1 year following initiation of therapy, is notable.[141–143] Treatment-related mortality as a consequence of myelosuppression and/or opportunistic infections attributable to immunosuppression occurred in up to 5% of all treated patients in some series with nucleoside analogues.

Factors predicting a better response to nucleoside analogues include younger age at start of treatment (<70 years), higher pretreatment hemoglobin (>9.5 g/dL), higher platelet count ($>75 \times 10^9$/L), disease relapsing off-therapy, and a long interval between first line therapy and initiation of a nucleoside analogue in relapsing patients.[141,146,152] There are limited data on the use of an alternate nucleoside analogue in previously treated patients in whom disease relapsed or who had resistance when not on cladribine or fludarabine therapy.[154,155] Three (75%) of four patients responded to cladribine after progression following an unmaintained remission with fludarabine, whereas only 1 (10%) of 10 with disease resistant to fludarabine responded to cladribine.[154] A response to fludarabine has been reported in two (33%) of six patients and disease stabilization in the remaining patients, in spite of an inadequate response or progressive disease, following cladribine therapy.[155]

Harvesting autologous blood stem cell grafts was successful on the first attempt in 14 of 15 patients who had not received nucleoside analogue therapy, as compared with 2 of 6 patients who received a nucleoside analogue.[156] A sevenfold increase in patients transforming to an aggressive lymphoma and a threefold increase in the development of myelodysplasia or acute myeloid leukemia was observed among patients who received a nucleoside analogue versus other therapies for their WM.[157] A meta-analysis of several trials in which patients with WM were treated with nucleoside analogues included patients who had previously received an alkylating agent, and the results showed a crude incidence of approximately 8% of developing a disease transformation event and approximately 5% for developing myelodysplasia or acute myeloid leukemia.[158] None of the risk factors—that is, sex, age, family history of WM, or B-cell malignancies, typical markers of tumor burden and prognosis, type of nucleoside analogue therapy (cladribine vs. fludarabine), time from diagnosis to nucleoside analogue use, nucleoside analogue treatment as primary or salvage therapy, or treatment with an oral alkylator (i.e., chlorambucil)—predicted the occurrence of transformation or development of myelodysplasia or acute myeloid leukemia in patients treated with a nucleoside analogue.[157]

CD20-Directed Antibody Therapy

Rituximab is a chimeric monoclonal antibody that targets CD20, a widely expressed antigen on lymphoplasmacytic cells in WM.[159] Several retrospective and prospective studies have indicated that rituximab, when used at standard doses (i.e., 4 weekly infusions of 375 mg/m^2/week) induced major responses in approximately 30% of previously treated and untreated patients.[160,161] Even patients who achieved minor responses benefited from rituximab by improved hemoglobin and platelet counts, as well as reduction of lymphadenopathy and/or splenomegaly.[160] The median time to treatment failure in these studies was found to range from 8 to 27+ months. Patients on an extended rituximab schedule consisting of 4 weekly courses at 375 mg/m^2/week, repeated 3 months later by another 4-week course have demonstrated major response rates of approximately 45%, with time to progression estimates of 16+ to 29+ months.[162,163]

In many patients with WM, a transient increase or flare of the serum IgM may occur immediately following initiation of rituximab treatment.[162,164,165] Such an increase does not herald treatment failure, and most patients will return to their baseline serum IgM level by 12 weeks. Some patients continue to show a prolonged increase in IgM despite an apparent reduction in their marrow tumor cells. However, patients with baseline serum IgM levels greater than 50 g/dL or serum viscosity greater than 3.5 cp may be particularly at risk for a hyperviscosity-related event, and plasmapheresis should be considered in these patients in advance of rituximab therapy.[164] Because of the decreased likelihood of response in patients with higher IgM levels, as well as the possibility that serum IgM and blood viscosity levels may abruptly rise, rituximab monotherapy should not be used as sole therapy for the treatment of patients at risk for hyperviscosity symptoms.[133,162,163]

About 5% to 10% of WM patients can develop rituximab intolerance, characterized by increasingly severe infusion reactions.[166]

The time to respond after rituximab is slow and exceeds 3 months on average. The time to best response in one study was 18 months.[163] Patients with baseline serum IgM levels less than 60 g/dL are more likely to respond, regardless of the underlying degree of marrow involvement by tumor cells.[162,163] An analysis of 52 patients who were treated with single-agent rituximab found the objective response rate was significantly lower in patients who had either low serum albumin (<35 g/L) or a serum monoclonal protein greater than 40 g/L.[167] The presence of both adverse prognostic factors was associated with a short time to progression (3.6 months). Patients who had normal serum albumin and relatively low serum monoclonal protein levels derived a substantial benefit from rituximab, with a time to progression exceeding 40 months.

The fully human anti-CD20 monoclonal antibody ofatumumab is effective on inducing responses in WM patients.[168] Ofatumumab-induced ORR of 59% with partial response rates of 41%. Very good partial or complete responses were not attained. The most common grade ≥3 adverse events included infusions reactions, chest pain, hemolysis and neutropenia. Ofatumumab can be used in patients who are intolerant to rituximab.[166]

Proteasome Inhibitors

In a retrospective study, 10 patients with refractory or relapsed WM were treated with bortezomib administered intravenously at a dose of 1.3 mg/m^2 on days 1, 4, 8, and 11 in a 21-day cycle for a total of 4 cycles. Most patients had been exposed to all other active agents for WM available at that time, and eight patients had received three or more regimens. Six of these patients achieved a partial response that occurred after a median of 1 month. The median time to progression in the responding patients is expected to exceed 11 months. Peripheral neuropathy occurred in three patients, and one patient developed severe paralytic ileus.[169] In a prospective study including 27 relapsed or refractory patients who received up to 8 cycles of bortezomib at 1.3 mg/m^2 on days 1, 4, 8, and 11, median serum IgM levels declined significantly, from 4.7 g/dL to 2.1 g/dL.[32] The ORR was 85%, with 10 and 13 patients achieving a minor (<25%) and major (<50%) decrease in IgM level, respectively. Responses occurred after a median of 1.4 months. The median time to progression for all responding patients in this study was 7.9 (range, 3 to 21.4+) months, and the most common grade III/IV toxicities were sensory neuropathies (22.2%), leukopenia (18.5%), neutropenia (14.8%), dizziness (11.1%), and thrombocytopenia (7.4%). Sensory neuropathies resolved or improved in nearly all patients following cessation of therapy. Twenty-seven patients with both untreated (44%) and previously treated (56%) disease received bortezomib, using the standard schedule until they either demonstrated progressive disease or 2 cycles beyond a complete response or stable disease.[170] The ORR was 78%, with major responses observed in 44% of patients. Sensory neuropathy occurred in 20 patients following 2 to 4 cycles of therapy. Among the 20 patients who developed a neuropathy, 14 showed resolution or improvement 2 to 13 months after therapy.

Combination Therapies

Because rituximab is not myelosuppressive, its use in combination with chemotherapy has been explored. A regimen of rituximab, cladribine, and cyclophosphamide in 17 previously untreated patients resulted in a partial response in 94% of patients with WM, including a complete response in 18%.[171] No patient had relapsed with a median follow-up of 21 months. The combination of rituximab and fludarabine was used in 43 patients, of whom 32 (75%) were previously untreated, which led to an ORR of 95.3%, with 83% of patients achieving a major response (i.e., 50% reduction in disease burden).[172] The median time to progression was 51.2 months in this series, and it was longer for those patients who were previously untreated and for those achieving a very good partial remission (i.e., 90% reduction in disease) or better. Hematologic toxicity was common: Grade 3 neutropenia and thrombocytopenia were observed in 27 and four patients, respectively. Two deaths occurred in this study as a result of pneumonia. Secondary malignancies, including transformation to aggressive lymphoma and development of myelodysplasia or acute myeloid leukemia, were observed in six patients. The addition of rituximab to fludarabine and cyclophosphamide has also been explored in previously treated patients, and four of five patients had a response.[173] In another combination study, rituximab along with pentostatin and cyclophosphamide was given to 13 patients with untreated and previously treated WM or LPL and resulted in a major response in 77% of patients.[174] The combination of rituximab, dexamethasone, and cyclophosphamide was used as primary therapy to treat 72 patients with WM, among whom a major response was observed in 74% of patients, with a 2-year progression-free survival rate of 67%.[175] Therapy was well tolerated, although one patient died as a result of interstitial pneumonia.

Two studies have examined cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) therapy in combination with rituximab (R-CHOP). In a randomized trial involving 69 patients, most of whom had WM, the addition of rituximab to CHOP resulted in a higher ORR (94% vs. 67%) and median time to progression (63 vs. 22 months) in comparison to patients treated with CHOP alone.[176] R-CHOP was also used in 13 patients with WM, 10 of whom had relapsed or refractory disease.[177] Among 13 evaluable patients, 10 patients achieved a major response (77%), including three complete and seven partial remissions. Two other patients achieved a minor response. Patients in a retrospective study of symptomatic WM received either R-CHOP; rituximab, cyclophosphamide, vincristine, and prednisone (R-CVP); or cyclophosphamide, prednisone, and rituximab (R-CP). The patients were similar in most pretreatment variables, and the ORRs to therapy were comparable among all three treatment groups—R-CHOP (96%), R-CVP (88%), and R-CP (95%)—although there was a trend for more complete remissions among patients treated with R-CVP and R-CHOP.[178] Adverse events attributed to therapy showed a higher incidence for neutropenic fever and treatment-related neuropathy for R-CHOP and R-CVP versus R-CP. The results of this study suggest that in patients with WM, the use of R-CP may provide treatment responses analogous to those of more intense cyclophosphamide-based regimens while minimizing treatment-related complications. The extended alkylator bendamustine has also been evaluated in combination with rituximab in both untreated and previously treated patients with WM. A randomized study by the German STiL Group examined bendamustine plus rituximab (Benda-R) versus R-CHOP in patients with untreated, indolent B-cell lymphomas including WM.[179] Patients with WM in this study showed similar overall responses (96% vs. 94%), though progression-free survival was significantly longer (69 vs. 29 months) in patients who received Benda-R versus R-CHOP. Treatment was also better tolerated in patients receiving Benda-R. In the relapsed or refractory setting, an ORR of 83% was observed with bendamustine in combination with a CD20 monoclonal antibody.[180] The median time to progression was 13 months in this study. Prolonged myelosuppression was more common in patients who had received prior nucleoside analogue therapy.

The use of two cycles of oral cyclophosphamide along with subcutaneous cladribine to 37 patients with previously untreated WM led to a partial response in 84% of patients, and the median duration of response was 36 months.[171] Fludarabine in combination with intravenous cyclophosphamide resulted in partial responses in 6 (55%) of 11 patients with WM with either primary refractory disease or who had relapsed on treatment.[181] The combination of fludarabine plus cyclophosphamide was also evaluated in 49 patients, 35 of whom were previously treated. Seventy-eight percent of the patients achieved a response, and the median time to treatment failure was 27 months.[182] Hematologic toxicity was frequent, and three patients died as a result of treatment-related toxicities. Two important findings in this study were the development of acute leukemia in two patients, histologic transformation to diffuse large B-cell lymphoma in one patient, and two cases of solid tumors (prostate and melanoma), as well as failure to be able mobilize stem cells for use as grafts for transplantation in four of six patients.

The combination of bortezomib, dexamethasone, and rituximab (BDR) as primary therapy in patients with WM resulted in an ORR of 96% and a major response rate of 83%.[183] The incidence of grade 3 neuropathy was approximately 30%, but this was reversible in most patients following discontinuation of therapy. An increased incidence of herpes zoster was also observed, prompting the prophylactic use of antiviral therapy. Alternative schedules for administration of bortezomib (i.e., once weekly at higher doses) in combination with rituximab in patients with WM have achieved ORRs of 80% to 90%.[184,185] The European Myeloma Network showed that transitioning bortezomib from twice-weekly intravenous dosing during the first cycle to weekly administration thereafter reduced grade 3 neuropathy to under 10% in patients treated with BDR.[186] There have been no studies addressing the safety and efficacy of subcutaneous bortezomib use in WM.

Carfilzomib, which is associated with a low risk of treatment-related peripheral neuropathy, has been evaluated in combination with rituximab and dexamethasone in patients with WM.[33] Carfilzomib was administered intravenously at 20 mg/m^2 (cycle 1), then 36 mg/m^2 (cycles 2 to 6), together with dexamethasone (20 mg) on days 1, 2, 8, and 9 as part of a 21-day cycle. As part of this regimen, rituximab 375 mg/m^2 was given on days 2 and 9 every 21 days. Maintenance therapy was given 8 weeks following induction therapy with intravenous carfilzomib (36 mg/m^2) and dexamethasone (20 mg) administered on days 1 and 2 and with rituximab 375 mg/m^2 on day 2 every 8 weeks for up to 8 cycles. The ORR with this regimen was 87.1% (one complete response, 10 very good partial responses, 10 partial responses, and 6 minimal responses) and was not impacted by *MYD88*^{L265P} or *CXCR4*^{WHIM} mutation status. With a median follow-up of 15.4 months, 20 patients remained progression-free. Grade ≥2 toxicities included asymptomatic hyperlipasemia (41.9%), reversible neutropenia (12.9%), and cardiomyopathy in 1 patient (3.2%) with multiple risk factors. Grade 2 treatment-related neuropathy occurred in one patient (3.2%). Declines in serum IgA and IgG were common, and some patients required intravenous immunoglobulin therapy for recurring sinus and bronchial infections.

The oral proteasome inhibitor ixazomib, in combination with dexamethasone and rituximab, was evaluated in 26 previously untreated patients with WM.[187,188] Ixazomib 4 mg PO and dexamethasone 20 mg PO were administered once weekly on days 1, 8, 15, with rituximab 375 mg/m2 IV on day 1, every 28 days for 6 cycles, and then every 56 weeks for 6 cycles. Rituximab was omitted from the first 2 cycles to minimize risk of IgM flare. ORR was 93%, major response rate was 77% and VGPR rate was 19%. The median PFS was 40 months. The adverse event profile of IDR was benign without grade 4 adverse events. The most common grade 3 adverse events were infusion reactions, hyperglycemia and infections.

Novel Therapeutics

The use of ibrutinib was recently approved by the US Food and Drug Administration for the treatment of symptomatic patients with WM. Ibrutinib targets BTK, a target of ibrutinib that is activated by MYD88^{L265P}.[42] A multicenter study examined the role of ibrutinib 420 mg PO once daily until disease progression or unacceptable toxicity in previously treated patients with WM (median 2 prior therapies, 40% refractory).[189,190] The ORR and major response rates were 91% and 79%, respectively. Decreased or resolved adenopathy was observed in 60% of patients with extramedullary disease, and five of nine patients with IgM-related peripheral neuropathy had symptomatic improvement. The 5-year PFS and OS rates were 54% and 93%, respectively. Although major response rates were lower in patients with *MYD88*^{WT} or with *CXCR4* mutations, it is not recommended that genotyping be used to select which patients should be placed on ibrutinib until further data are available. Grade ≥2 treatment-related toxicities included neutropenia (24%) and thrombocytopenia (13%) that were more common in heavily pretreated patients, atrial fibrillation associated with a prior history of arrhythmia (10%), and bleeding associated with procedures (3%). Treatment-related infections were infrequent.

Similar results were observed in two separate studies, one in 31 WM patients who were refractory to rituximab (INNOVATE-C), and in 30 previously untreated WM patients. In both studies, ibrutinib was administered at a dose of 420 mg PO once daily until disease progression or unacceptable toxicity. In the INNOVATE-C study, ORR was 90%, major response rate was 71% and VGPR rate was 13%, with an 18-month PFS rate of 86%.[191] In previously untreated patients, the ORR was 100%, major response rate was 83% and VGPR rate was 20%, with an 18-month PFS rate of 92%.[192] *CXCR4* mutations were associated with longer time to response and lower rate of response to ibrutinib monotherapy. The adverse event profile in these studies was similar to what had been previously reported. These results consolidated ibrutinib as a standard of care in WM patients.

In the randomized portion of the INNOVATE study in which 75 WM patients were randomized to ibrutinib and rituximab (ibrutinib-R) and 75 to placebo and rituximab (placebo-R).[193] Ibrutinib was administered at 420 mg PO once daily until disease progression or unacceptable toxicity, and rituximab at a dose of 375 mg/m^2 IV given once weekly for 4 weeks followed by a second 4-week round 4 months later. The combination of ibrutinib-R was associated with higher rates of major response (72% vs. 32%) and 30-month PFS rates (82% vs. 28%) than placebo-R. The rate of IgM flare and infusion reactions to rituximab were lower in the patients who received ibrutinib-R. *CXCR4* mutations also seemed to adversely affect depth and duration of response in WM patients treated with ibrutinib-R. Given the lack of an ibrutinib-placebo arm, the benefit of the addition of rituximab to ibrutinib is currently unclear.

Acalabrutinib and zanubrutinib are novel BTK inhibitors with higher specificity towards BTK than ibrutinib. A phase II study evaluated acalabrutinib 100 mg PO BID in 106 (14 treatment naïve and 92 previously treated) WM patients.[194] Acalabrutinib therapy was associated with an ORR of 93% in both treatment-naïve and previously treated patients. The 2-year PFS rate was 90% and 82%, respectively. The most common serious adverse events included respiratory infections (14%), cellulitis (3%) and sepsis (3%). One treatment-related death caused by intracranial hematoma was reported.

The ASPEN study randomized 201 (37 treatment-naïve and 164 previously treated) WM patients to zanubrutinib 160 mg PO BID (n = 102) versus ibrutinib 420 mg PO QD[195] (n = 99). The primary end point of the study was to show a superiority of zanubrutinib over ibrutinib on very good partial response rates assessed by an independent review committee. The rates of very good partial response for zanubrutinib and ibrutinib were 28% and 19%, respectively (P = .09). No patients attained a complete response. There were no differences between groups in ORR or PFS. Zanubrutinib was associated with lower incidence of atrial fibrillation (2% vs. 15%) but higher incidence of neutropenia (29% vs. 13%) than ibrutinib.

Maintenance Therapy

The outcome of rituximab-naïve patients who were either observed or received maintenance rituximab categorical responses has been examined in several retrospective studies, which suggested PFS and OS benefits.[196] A prospective study by the German STiL Group examining the role of maintenance rituximab is ongoing.[197] Preliminary results suggest that there was no PFS benefit from maintenance rituximab compared with observation after induction therapy with Benda-R (101 vs. 82 months, respectively; P = .32). In subset analyses, patients older than 65 and with intermediate/high-risk disease seemed to benefit from maintenance rituximab. Also, patients who attained minor response to induction were not included in the randomization portion of the study.

High-Dose Therapy and Stem Cell Transplant

The European Bone Marrow Transplant Registry (EBMT) reported the largest experience for both autologous as well as allogeneic SCT in WM.[198,199] Among 158 patients with WM receiving an autologous SCT, which included primarily relapsed or refractory patients, the 5-year progression-free and overall survival rates were 39.7% and 68.5%, respectively.[198] Nonrelapse mortality at 1 year was 3.8%. Chemorefractory disease and the number of prior lines of therapy at the time of the autologous SCT were the most important prognostic factors for progression-free and overall survival. In the allogeneic SCT experience from the EBMT, the long-term outcomes of 86 patients with WM were reported.[199] A total of 86 patients received an allograft following either myeloablative or reduced-intensity conditioning. The median age of patients in this series was 49 years, and 47 patients had undergone three or more previous lines of therapy. Eight patients had failed prior autologous SCT. Fifty-nine patients (68.6%) had chemotherapy-sensitive disease at the time of allogeneic SCT. Nonrelapse mortality rates at 3 years were 33% for patients receiving a myeloablative transplant and 23% for those who received reduced-intensity conditioning. The ORR was 75.6%. The relapse rates at 3 years were 11% for myeloablative and 25% for those recipients receiving reduced-intensity conditioning. Five-year progression-free and overall survival for WM patients who received a myeloablative allogeneic SCT were 56% and 62%, respectively, and for patients who received reduced intensity conditioning, the rates were 49% and 64%, respectively. The occurrence of chronic graft-versus-host disease was associated with improved progression-free survival and suggested the existence of a clinically relevant graft-versus-WM effect in this study. A consensus document on the role of transplantation in WM was presented at the 2017 ASH Annual Meeting.[200] Consensus was reached, among other topics, on the following: (1) Autologous SCT is not appropriate as part of first line therapy in patient responding to induction therapy; (2) Autologous SCT is appropriate following second or subsequent relapses in high-risk patients with chemosensitive disease; (3) SCT should not be considered in BTK inhibitor-naïve patients, provided that BTK inhibitors are available. Allogeneic SCT should be considered in highly selected WM cases and preferably in the context of a clinical trial.

Treatment Recommendations During the COVID-19 Pandemic

The SARS-CoV-2-associated coronavirus disease 2019 (COVID-19) pandemic has affected individuals across the globe, including patients with blood cancers. There are mounting data suggesting an increased risk of contracting and severe complications with COVID-19. The International Workshop for WM provided recommendations for the management of WM patients during the COVID-19 pandemic.[201] Some of the recommendations include, but are not limited to:

- Increasing the threshold for treatment initiation and preferentially pursue watchful waiting whenever possible.
- If therapy is needed, BTK inhibitors or chemoimmunotherapy are reasonable options.
- For patients who attained an excellent response with chemoimmunotherapy, a reduced number of cycles could be considered.
- The use of maintenance rituximab should be avoided.
- Proactive support with growth factors, antibiotics, intravenous immunoglobulins and vaccines is highly encouraged.

Response Criteria in Waldenström Macroglobulinemia

Table 92.3 summarizes the response categories and criteria for progressive disease in WM based on the most recent consensus recommendations.[202] The term *overall response* is used to characterize all responses, including minor responses. *Major responses* include partial, very good partial, and complete responses. The attainment of very good partial or complete responses is associated with improved progression-free survival.[161,172,183,186,203] Response assessments in WM rely primarily on serum IgM or IgM paraprotein levels, though complete responses require disappearance of the IgM monoclonal protein, and resolution of evidence of BM and/or extramedullary disease.[202] An important concern with the use of IgM as a surrogate marker of disease is that it can fluctuate independent of tumor cell killing with some agents. By way of example, rituximab can induce a flare in serum IgM levels, whereas bortezomib and ibrutinib can suppress IgM levels independent of tumor cell killing in some patients, a phenomenon referred to as *IgM discordance*.[164,165,169,196,204,205] Moreover, with selective B cell–depleting agents such as rituximab, residual IgM-producing plasma cells are spared and persist, thus potentially skewing the relative response and assessment to treatment.[206]

Course and Prognosis

WM typically presents as an indolent disease. The presence of 6q deletions may have prognostic significance, although this is disputed.[19,20] Age is an important prognostic factor (>65 years),[207–209] but it is influenced by comorbidities. Anemia that reflects both marrow involvement and the serum level of the IgM monoclonal protein (because of the impact of IgM on intravascular fluid retention) has emerged as a strong adverse prognostic factor with hemoglobin levels of less than 9 to 12 g/dL associated with decreased survival in several series.[207–209] Other cytopenias also may be significant predictors of survival.[208] The precise level of cytopenias with prognostic significance has not been determined. Some series have identified a platelet count of less than 100 to 150 × 10^9/L and a granulocyte count of less than

TABLE 92.3 **Summary of Consensus Response Criteria for Waldenström Macroglobulinemia**

Response Type	Abbreviation	Criteria
Complete response	CR	Absence of serum monoclonal IgM protein by immunofixation Normal serum IgM level Complete resolution of extramedullary disease (i.e., lymphadenopathy/splenomegaly if present at baseline) Morphologically normal bone marrow aspirate and trephine biopsy
Very good partial response	VGPR	Monoclonal IgM protein is detectable 90% reduction in serum IgM level from baseline or normalization of serum IgM level Complete resolution of extramedullary disease (i.e., lymphadenopathy/splenomegaly if present at baseline) No new signs or symptoms of active disease
Partial response	PR	Monoclonal IgM protein is detectable ≥50% but <90% reduction in serum IgM level from baseline Reduction in extramedullary disease (i.e., lymphadenopathy/splenomegaly if present at baseline) No new signs or symptoms of active disease
Minor response	MR	Monoclonal IgM protein is detectable ≥25% but <50% reduction in serum IgM level from baseline No new signs or symptoms of active disease
Stable disease	SD	Monoclonal IgM protein is detectable <25% reduction and <25% increase in serum IgM level from baseline No progression in extramedullary disease (i.e., lymphadenopathy/splenomegaly) No new signs or symptoms of active disease
Progressive disease	PD	>25% increase in serum IgM level from lowest nadir (requires confirmation) and/or progression in clinical features attributable to the disease

1.5×10^9/L as independent prognostic factors.[208,209] The number of cytopenias in a given patient has been proposed as a prognostic factor.[208] Serum albumin levels also correlate with survival in patients with WM in some studies, using multivariate analyses.[208,210] Elevated serum β_2-microglobulin levels (>3 to 3.5 g/dL) have also been shown to have strong prognostic correlation in WM.[208–211] Several scoring systems have been proposed that are based on these analyses (Table 92.4), including the International Prognostic Scoring System for Waldenström macroglobulinemia (IPSSWM), which incorporates five adverse covariates: advanced age (>65 years), hemoglobin $\leq$11.5 g/dL, platelet count $\leq 100 \times 10^9$/L, β_2-microglobulin greater than 3 mg/L, and serum monoclonal protein concentration greater than 7.0 g/dL.[212] Among 537 patients with WM evaluated in the development of IPSSWM, low-risk patients (27%) presented with no or one of the adverse characteristics and advanced age; intermediate-risk patients (38%) presented with two adverse characteristics or only advanced age; and high-risk patients (35%) presented with more than two adverse characteristics. Five-year survival rates for these three patient groups were 87%, 68%, and 36%, respectively. Importantly, the IPSSWM retained its prognostic significance in subgroups defined by age and treatment with alkylating agent and nucleoside analogues. Despite its prognostic value in WM patients treated with chemotherapy agents, the prognostic value of the IPSSWM has not been validated in WM patients on BTK inhibitors. Furthermore, the IPSSWM is not used to inform time to treat or treatment selection. Recent data from the Surveillance, Epidemiology, and End Results (SEER) database involving 7744 patients with WM showed that the relative survival of patients with WM has improved over time. Patients diagnosed during 2001–2010 had higher 5-year (78% vs. 67%) and 10-year (66% vs. 49%) relative survival rates versus patients diagnosed during 1980–2000. A Greek study that included 345 patients with WM failed to show any overall or cause-specific survival improvement in recent years, though the study might have been underpowered to detect any expected benefit.[211] A Swedish study of 1555 patients diagnosed with WM between 1980 and 2005 showed that the 5-year relative survival rate improved from 57% in 1980–1985 to 78% in 2001–2005.[213]

FUTURE DIRECTIONS

WM remains an incurable disease and, therefore, novel approaches that would improve response rates and survival while decreasing toxicity are being actively investigated.

A number of clinical trials are currently evaluating BTK inhibitors in combination with chemotherapy, proteasome inhibitors and other targeted agents, such as the BCL2 antagonist venetoclax, the anti-CXCR4 inhibitor mavorixafor and the anti-CD38 monoclonal antibody daratumumab. Preliminary data from a phase II study evaluating single agent venetoclax have reported an ORR of 90% with an 18-month PFS rate of 82% in previously treated WM patients.[214] Single agent daratumumab was associated with a lower-than-expected ORR of 23% in previously treated WM patients but preclinical data have suggested synergism with BTK inhibitors.[215,216]

The emergence of *BTK C481S* mutations has been associated with the development of resistance to covalent BTK inhibitors. Noncovalent BTK inhibitors that do not interact with C481, such as pirtobrutinib and ARQ531, are being investigated in WM patients progressing or intolerant to covalent BTK inhibitors.[217,218]

Other targets of clinical interest include IRAK/IRAK4, HCK and CD19.

TABLE 92.4 Prognostic Scoring Systems in Waldenström Macroglobulinemia

Study	Adverse Prognostic Factors	Number of Groups	Survival
Gobbi et al.[207]	Hgb <9 g/dL	0–1 prognostic factors	Median: 48 months
	Age >70 years	2–4 prognostic factors	Median: 80 months
	Weight loss		
	Cryoglobulinemia		
Morel et al.[208]	Age ≥65 years	0–1 prognostic factors	5-year: 87% of patients
	Albumin <4 g/dL	2 prognostic factors	5-year: 62%
	Number of cytopenias:	3–4 prognostic factors	5-year: 25%
	Hgb <12 g/dL		
	Platelets $<150 \times 10^9$/L		
	WBC $<4 \times 10^9$/L		
Dhodapkar et al.[209]	β_2M ≥3 g/dL	β_2M <3 mg/dL + Hgb ≥12 g/dL	5-year: 87% of patients
	Hgb <12 g/dL	β_2M <3 mg/dL + Hgb <12 g/dL	5-year: 63%
	IgM <4 g/dL	β_2M ≥3 mg/dL + IgM ≥4 g/dL	5-year: 53%
		β_2M ≥3 mg/dL + IgM <4 g/dL	5-year: 21%
Dimopoulos et al.[210]	Albumin ≤3.5 g/dL	Albumin ≥3.5 g/dL + β_2M <3.5 mg/dL	Median: NR
	β_2M ≥3.5 mg/L	Albumin ≤3.5 g/dL + β_2M <3.5 or	Median: 116 months
		β_2M 3.5–5.5 mg/dL	Median: 54 months
		β_2M >5.5 mg/dL	
Morel et al.[212]	Age >65 years	0–1 prognostic factors (excluding age)	5-year: 87% of patients
	Hgb <11.5 g/dL	2 prognostic factors (or age >65 years)	5-year: 68%
	Platelets $<100 \times 10^9$/L	3–5 prognostic factors	5-year: 36%
	β_2M >3 mg/L		
	IgM >7 g/dL		

β_2M, β_2-microbloulin; *Hgb*, hemoglobulin; *IgM*, immunoglobulin M; *NR*, not reported; *WBC*, white blood cell count.

CHAPTER 93

IMMUNOGLOBULIN LIGHT-CHAIN AMYLOIDOSIS (PRIMARY AMYLOIDOSIS)

Morie A. Gertz, Francis K. Buadi, Martha Q. Lacy, and Suzanne R. Hayman

Amyloidosis is defined as the clinical syndrome associated with deposition of amyloid. Amyloid in tissue is defined by its tinctorial properties of a homogeneous, eosinophilic, hyaline material when viewed by hematoxylin and eosin staining. Amyloid stains specifically with Congo red, demonstrating a deep pink amorphous composition. Although Congo red staining is the sine qua non for the diagnosis of amyloid, many pathology laboratories prefer the use of sulfated Alcian blue or crystal violet for screening. A second requirement is that the Congo red-positive histologic finding must demonstrate apple-green birefringence when observed under polarized light.[1] A positive crystal violet or sulfated Alcian blue stain should be confirmed with Congo red staining.

The term *amyloid* is a misnomer. The term was first used in 1838 by a German botanist because the tissue stained blue with iodine and was incorrectly thought to be starch-like, thus the terminology of *amyloid*. In Vienna, Rokitansky believed that the material was not starch but rather made of lipid composition and used the term *lardaceous degeneration* for amyloid. Both were incorrect because all forms of amyloid appear to be protein-derived.[2]

By electron microscopy, amyloid has been shown to be fibrillar in origin with an approximate diameter of 9.5 nm, and linear nonbranching and comprised of protofilaments (Fig. 93.1). The Congo red binding occurs because the protein misfolds from the physiologic configuration of the α-helix into a β-pleated sheet, which is directly responsible for its insolubility and resistance to proteolysis. Amyloid is highly resistant to solubilization unless it is subjected to the harshest denaturation conditions. This insolubility in the physiologic solution likely contributes to the amyloid's ability to disrupt normal organ function and leads to the clinical disease amyloidosis, the clinical syndrome associated with deposition of amyloid.[3]

EPIDEMIOLOGY

The incidence of immunoglobulin light-chain amyloidosis is estimated to be approximately 1.2 per 100,000 person years. The rate of the disease is not increasing. One would expect 3852 new cases of amyloid light-chain (AL) amyloidosis in the United States each year. It is the cause of death in 0.58 of 1000 recorded deaths and is responsible for 0.8% of end-stage renal disease. At the Mayo Clinic, AL amyloidosis represents 9% of all patients seen with monoclonal gammopathies.[4,5] Half of these patients have over 10% plasma cells in the bone marrow fulfilling criteria for smoldering multiple myeloma. At the time of diagnosis of amyloidosis, if multiple myeloma is not present it will only be developed subsequently in 0.4% of patients.[4] At the time of diagnosis of light-chain amyloidosis 8% have been found to have coexisting multiple myeloma.[5] AL amyloidosis represents 52% of all patients seen with amyloidosis. However, hereditary amyloidosis now accounts for 5% of patients, localized amyloidosis 9% of patients, *wild-type TTR* (TTRwt) (senile systemic amyloidosis) 32% of patients, and secondary amyloidosis 1% of patients. All these forms of amyloidosis have the same tinctorial properties in the histologic section and must be distinguished using other techniques. The reported overall mean age-adjusted mortality rate from amyloidosis as the underlying cause of death has doubled from 1.77 to 3.96 per 100,000 population.[6]

The cause of the plasma cell dyscrasia that underlies AL amyloidosis remains unknown. There does not appear to be a linkage to any specific occupation or toxic chemical exposure. No environmental agents have been linked to the development of amyloidosis. However, the Veterans Administration in the United States considers amyloidosis in a veteran who was exposed to Agent Orange (dioxin) during the Vietnam era to have a service-connected illness.[7]

Amyloidosis may be systemic or localized. The localized forms do not require systemic chemotherapy. The distinction is, therefore, important so that patients for whom chemotherapy will not be of benefit are not inappropriately subjected to this form of therapy. Localized amyloidosis can be suspected, usually based on the location of the deposits, as discussed in the "Clinical Manifestations" section below.[8]

Familial amyloidosis is, for most patients, caused by an inherited mutation of transthyretin (TTR). It is difficult to distinguish from light-chain amyloidosis because the clinical manifestations may be quite similar. Other inherited forms of amyloidosis have been associated with apolipoprotein A1 mutations, fibrinogen A α mutations, and mutations of gelsolin.[9]

Secondary systemic amyloidosis is amyloidosis that is usually a consequence of a sustained inflammatory process. The frequency of symptomatic secondary systemic amyloidosis has been in a sharp decline for the past decade. Previously, secondary systemic amyloidosis was a consequence of an uncontrolled inflammatory process, typically inflammatory polyarthropathies, such as juvenile rheumatoid arthritis, psoriatic arthritis, or ankylosing spondylitis. Another cause was long-standing inflammatory bowel disease. Amyloidosis as a consequence of these inflammatory processes has fallen sharply with the introduction of biologic agents that function as inhibitors of interleukin-1, interleukin-6, and inhibitors of tumor necrosis factor α (TNF-α). Sporadic patients are seen with multiple cutaneous abscesses, usually as a result of subcutaneous injection of contaminated narcotics. Patients can also be seen with chronic infections related to paraplegia or quadriplegia. Rare patients with lifelong bronchiectasis related to cystic fibrosis can develop systemic amyloidosis. There are also forms of inherited secondary amyloidosis associated with familial inflammatory syndromes such as familial Mediterranean fever or mutations of the TNF receptor gene (so-called TNF receptor-associated periodic syndrome).[10]

PATHOBIOLOGY OF THE DISEASE

In immunoglobulin light-chain amyloidosis, the immunoglobulin fragments have specific thermodynamic instability that causes them to misfold into the insoluble amyloid configuration. The injection of immunoglobulin light chains purified from the urine of patients with multiple myeloma will not produce amyloid when injected into mice. However, when the light chains are extracted from the urine of patients with light-chain amyloidosis and injected into mice, it will produce amyloid deposits and organ dysfunction, suggesting that the specifics of the immunoglobulin light chain are important in determining its propensity to misfold into amyloids. Monoclonal immunoglobulin light chains can be converted in vitro to amyloid by in vitro digestion with pepsin. Historically, before it was clearly

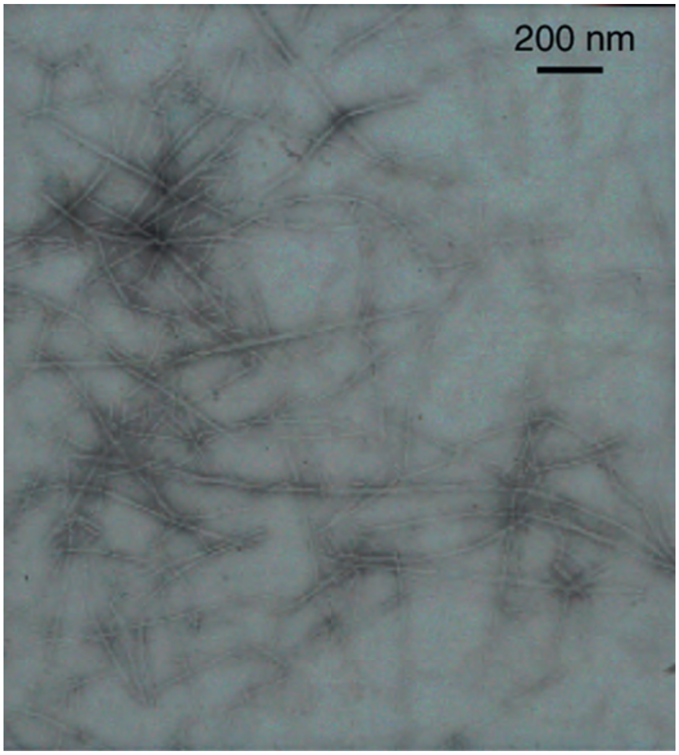

Figure 93.1 ELECTRON MICROGRAPH DEMONSTRATING THE CLASSIC FIBRILS OF AMYLOID.

understood that amyloidosis was derived from a plasma cell dyscrasia with the development of “toxic” immunoglobulin light chains, the term *primary amyloidosis* was used as a consequence of the lack of understanding of the pathophysiology. This term should be abandoned, and the term *immunoglobulin light-chain amyloidosis* or *AL amyloidosis* (amyloid light chain) should be used. Many forms of localized amyloidosis are also derived from immunoglobulin light chains, but there is no evidence of a systemic plasma cell dyscrasia, and anti-plasma cell chemotherapy is contraindicated. Virtually all patients with systemic AL amyloidosis have a demonstrable clonal plasma cell disorder. In monoclonal gammopathy of undetermined significance (MGUS) and multiple myeloma, two-thirds of the immunoglobulin light chains are κ type. In AL amyloidosis, nearly three-fourths of the light chains are of λ origin (Fig. 93.2), suggesting that there is a greater propensity for λ light chains to misfold into amyloid configuration. The λ_6 subgroup of light chains is exclusively associated with amyloid deposition. There are also abnormalities in amyloid-associated germline gene use. A preferential use of variable lambda (VL) germline genes is noted for ALκ and AL λ patients. There is a significant correlation between the use of V λ_6 germline, 6a, and renal involvement as well as the λ_3 gene, 3r, with soft tissue AL. Identification of the clonal VL gene in AL has important implications regarding clinical outcome.[11]

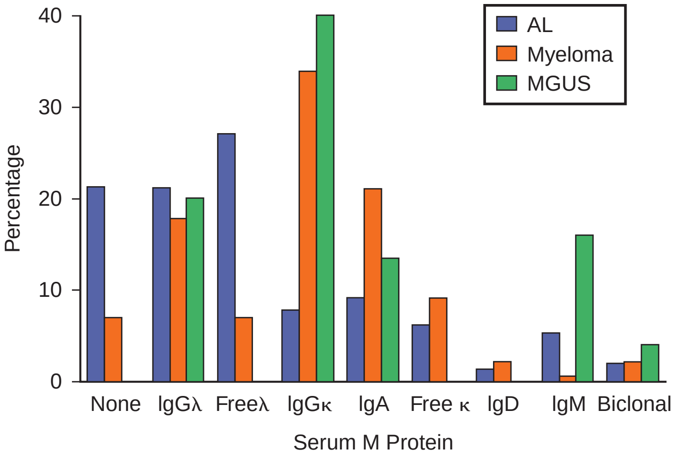

Figure 93.2 DISTRIBUTION OF HEAVY- AND LIGHT-CHAIN PROTEINS IN MYELOMA, MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE, AND AMYLOID LIGHT-CHAIN AMYLOIDOSIS. *AL*, Amyloid light chain; *Ig*, Immunoglobulin; *MGUS*, monoclonal gammopathy of undetermined significance.

Chromosomal aberrations of the plasma cells in AL amyloidosis have also been recognized. Interphase fluorescence in situ hybridization (FISH) has detected a gain of 1q21, predicting a poor overall survival, and is an independent prognostic factor. Patients with t(11;14) have a longer median overall survival. The t(11;14) is associated with lower response rates to bortezomib-containing regimens. This translocation is seen in 50% of AL patients compared to 15% of myeloma patients. This high prevalence has led to the exploration of venetoclax as a possible therapy for AL amyloidosis. Translocation (11;14) suppresses the emergence of sub-clones and likely accounts for the lower frequency of −17p and 1q+ in AL amyloidosis. Deletion 13q14 and hyperdiploidy are prognostically neutral. Because the incidence of t(11;14) is so high in AL amyloidosis the possibility that venetoclax would be active is rational. Clinical trials are underway to test venetoclax but pending results of these trials it would be reasonable to consider venetoclax in patients who failed the first- or second-line therapies. There are case reports of venetoclax-induced complete response in patients with AL amyloidosis. The combination of daratumumab and venetoclax has been reported to produce both hematological complete response and organ response in a patient with cardiac, renal, peripheral, and autonomic nervous system involvement.[12]

The pathobiology of organ dysfunction associated with amyloidosis has long been assumed to be caused by the direct effect of amyloid protein deposition in tissues. However, there is increasing evidence that the light chains themselves have a toxic effect on tissues as a soluble mediator. A zebrafish model of human light-chain cardiotoxicity has demonstrated that the injection of light chains results in impaired cardiac function, pericardial edema, and increased cell death. Mitogen-activated protein (MAP) kinase activation may mediate this cardiotoxicity, and p38 MAP kinase inhibition reduces cell death and improves cardiac function.[13]

Amyloidosis and multiple myeloma both share the presence in the bone marrow of a clonal population of plasma cells. The number of plasma cells and the immunoglobulin light chains that they produce are both important for prognosis. Patients who have an increased number of plasma cells in the bone marrow with light-chain amyloidosis have a worse prognosis and shorter overall survival, regardless of whether they manifest any of the clinical criteria associated with multiple myeloma, such as hypercalcemia, renal insufficiency, anemia, or destructive bone lesions. There appears to be no survival difference between patients who have an elevated plasma cell count over 10% in their bone marrow and whether they have overt (CRAB—hyperCalcemia, Renal insufficiency, Anemia, Bone lesions) symptoms of myeloma. The therapeutic import has led our group to recommend induction chemotherapy for patients with AL amyloidosis at a diagnosis prior to consolidative, autologous stem cell transplantation.[14]

CLINICAL MANIFESTATIONS

Patient 1

Patient 1 is a 46-year-old man who, 10 months prior to diagnosis, began to develop cramping abdominal pain associated with an unexplained 45-lb weight loss. Four months later, he began to develop episodes of orthostatic syncope and was documented to have an orthostatic drop in blood pressure from systolic 110 mmHg in supine to 66 mmHg when standing. As a consequence of his abdominal cramping, the patient underwent endoscopy and colonoscopy. Biopsies were obtained from the duodenum, proximal jejunum, colon, and rectum, all of which demonstrated amyloid deposits. Subsequently, a bone marrow biopsy was performed that showed 4% clonal plasma cells. A subcutaneous fat aspirate was positive for amyloid. The plasma cells showed a CCND1/IgH fusion t(11;14). The patient's hemoglobin level was normal, as were his creatinine, alkaline phosphatase, and urinary protein. The patient had a λ free light chain level of 92.8 mg/L, κ free light chain of 10.9 mg/L, and a ratio of 0.12.

Comment on Patient 1

This patient presented with amyloid autonomic neuropathy, leading to gastrointestinal (GI) tract dysmotility and pain as well as orthostatic hypotension. There was clear-cut evidence of a low-volume plasma cell dyscrasia. Orthostatic hypotension causing lightheadedness is a very nonspecific complaint, and syncope owing to amyloid orthostatic hypotension is easily overlooked because of its infrequency.

Patient 2

A 61-year-old man with a known immunoglobulin G λ MGUS of 0.6 mg/dL was monitored on an annual basis with no change in the level of the monoclonal protein over a period of 3 years. He developed progressive fatigue and shortness of breath. He was evaluated by a cardiologist, and his echocardiogram showed thickening that was interpreted to be related to hypertension, with a normal ejection fraction. The patient was placed on lisinopril and did not improve. He returned and underwent catheterization with coronary angiography. His coronary arteries were normal, and he was diagnosed with deconditioning. His dyspnea continued, and he was referred to a pulmonologist, who recognized the long-standing monoclonal gammopathy and obtained light chain studies that showed a λ light chain of 410 mg/L and κ of 10 mg/dL. The patient underwent a subcutaneous fat aspiration that demonstrated amyloid deposits, which, by mass spectroscopy, were found to be of λ origin. At this point, the patient had New York Heart Association class IV heart failure; he died 3 months thereafter.

Comment on Patient 2

This case is an example of a classic failure to recognize that patients with monoclonal gammopathies should have AL amyloidosis included in the differential diagnosis. The fact that the monoclonal protein was stable would certainly argue against the development of multiple myeloma, but light-chain amyloidosis regularly occurs without any change in the M component over time. The failure to recognize the patient's progressive fatigue and shortness of breath as cardiac amyloid is not unusual. The echocardiographic findings of thickening were interpreted as being caused by hypertension, but, in fact, they were caused by infiltrative cardiomyopathy, and the cardiac catheterization and angiogram without an endomyocardial biopsy led to a missed diagnosis. Only an increased index of suspicion in patients with a known monoclonal protein allowed this diagnosis to be confirmed.

One of the major difficulties in the diagnosis of amyloidosis is that there is virtually no blood test or imaging study that is diagnostic of the disease. The most common symptoms associated with amyloidosis are fatigue, lower extremity edema (may be cardiac or renal), unexplained weight loss (often leading to search for occult malignancy), exertional dyspnea, orthostatic hypotension, and paresthesias. These symptoms are quite vague, and in a general medical practice, there are hundreds of disorders that are far more common and are responsible for light-chain amyloidosis. As noticed in Patient 2, the fatigue, which is often caused by early cardiac amyloid but is not associated with overt congestive heart failure, can be missed. Cardiac amyloidosis is a classic form of heart failure with a preserved ejection fraction owing to the restrictive physiology associated with amyloidosis.[15] The typical echocardiographic findings include thickening of the interventricular septum due to infiltration with amyloid (usually >12 mm), a decline in global longitudinal strain (normal is greater than −18%) and the slowing of filling of the ventricles during diastole due to non-compliant walls.

Edema in amyloidosis may be a manifestation of high right-sided filling pressures, leading to lower extremity edema, or it may be a consequence of renal involvement with the nephrotic syndrome (peripheral edema, hypoalbuminemia, hyperlipidemia, and proteinuria). Even when nephrotic range proteinuria is seen, amyloidosis, which is known to cause nephrotic syndrome in 10% of adults who are nondiabetic, is infrequently considered in the differential diagnosis, which would include minimal change glomerulopathy, as well as membranous and membranoproliferative glomerulopathy.[16,17]

The physical findings that are known to be associated with light-chain amyloidosis include enlargement of the tongue (15%) (Fig. 93.3) and periorbital purpura (12%). These findings are highly specific when recognized. However, although they are highly specific, they lack sensitivity because nearly 80% of patients with amyloidosis lack both of these physical features. It is common for an enlarged tongue in amyloid to be misdiagnosed as suspected glossal cancer or a manifestation of acromegaly. Many patients with significant tongue enlargement needlessly undergo a painful and often hemorrhagic tongue biopsy, which could be avoided if the diagnosis was considered. Patients with enlargement of the tongue frequently have major indentations on the underside of their tongue from their teeth and the continuous pressure that the tongue exerts against their lower jaw. The purpura is also quite specific, and the patient often will note the

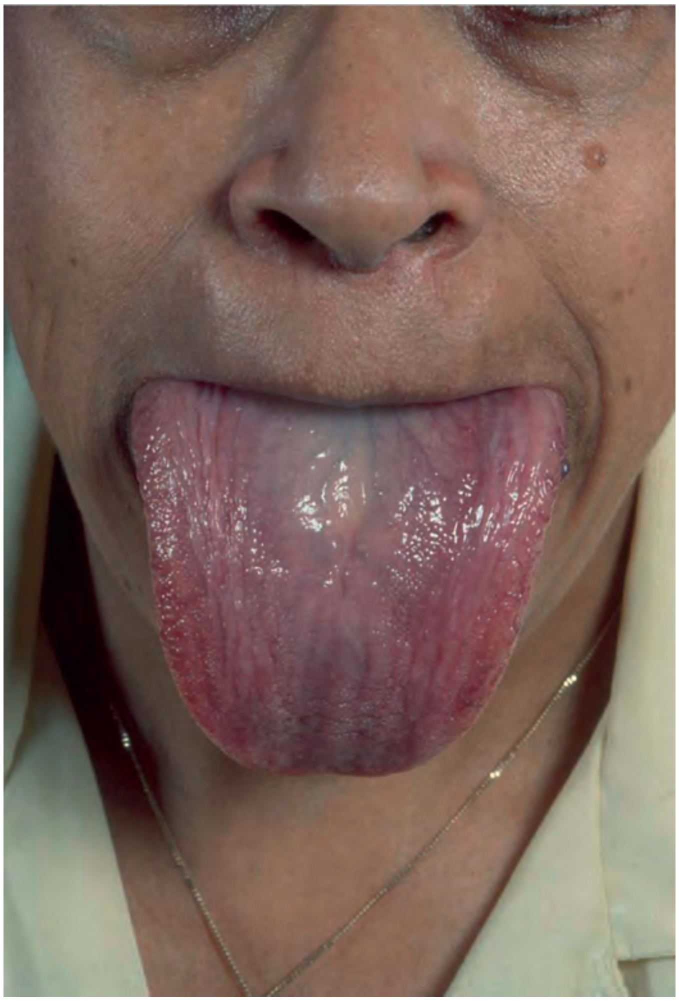

Figure 93.3 ENLARGED TONGUE INFILTRATED BY AMYLOID DEPOSITS.

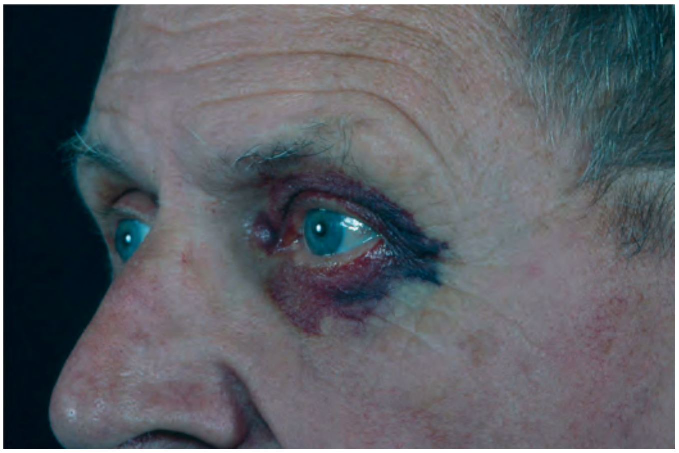

Figure 93.4 CLASSIC AMYLOID PURPURA.

development of purpura simply by rubbing of the eyelids. However, these patients often undergo an evaluation for a coagulation disorder or are simply reassured that purpura is benign, and the physical findings do not trigger an investigation for light-chain amyloidosis (Fig. 93.4).[18]

Hepatomegaly is seen in approximately 10% of patients with amyloidosis, but it is nonspecific, and an imaging of the liver will show homogeneous enlargement without filling defects. Occasionally, patients will have a widespread vascular amyloid that will result in claudication of the calf, buttock, upper extremities, and jaw. Occasionally, these patients will undergo temporal artery biopsy, which, when appropriately stained, will show amyloid. More often, these patients will be given an empiric diagnosis of polymyalgia rheumatica and be placed on corticosteroids without appropriate screening. The rarest physical finding in amyloidosis is periarticular infiltration of the synovium in the upper extremities, leading to the "shoulder pad" sign (Fig. 93.5). This causes a continuous, chronic, low-grade pain caused by the periarticular infiltration. Diagnosis in this setting requires arthrocentesis and the demonstration of Congo red-positive deposits in the synovial fluid.[19]

LABORATORY MANIFESTATIONS

If the symptoms of amyloidosis are so vague as not to be helpful and the physical findings are specific but not sensitive, when should a clinician suspect amyloidosis and aggressively pursue this rare disorder? Amyloidosis should be considered in any patient who presents with (1) nephrotic range proteinuria; (2) fatigue, which may have a cardiac basis, including heart failure with preserved ejection fraction or restrictive cardiomyopathy; (3) unexplained hepatomegaly; (4) a peripheral neuropathy resembling chronic inflammatory demyelinating polyneuropathy (CIDP); and (5) "atypical" smoldering multiple myeloma or MGUS with unexplained fatigue, weight loss, and edema. Consulting patients with any one of these five syndromes should lead to the placement of light-chain amyloid in the differential diagnosis, and screening should commence.[20]

Because all patients with systemic immunoglobulin light-chain amyloidosis have a plasma cell dyscrasia, the initial step should be screening by performing immunofixation of the serum, immunofixation of the urine, and an immunoglobulin free light chain assay. Results of one of these three tests will be abnormal in 99% of patients with light-chain amyloidosis. If results of these three tests are negative, the likelihood is that one of the following conditions exists: (1) The patient does not have amyloidosis; (2) the chance of immunoglobulin light-chain amyloidosis is only 1%; (3) the patient has systemic amyloidosis, but it is not of immunoglobulin light-chain origin (familial amyloid or senile systemic amyloid); or (4) the amyloidosis is localized.[21]

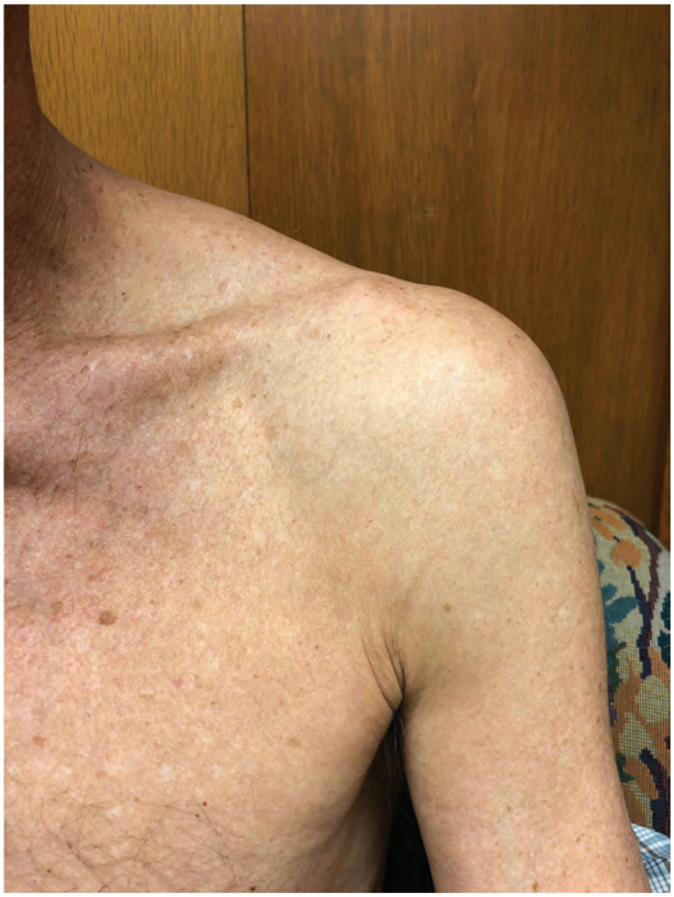

Figure 93.5 SHOULDER PAD SIGN.

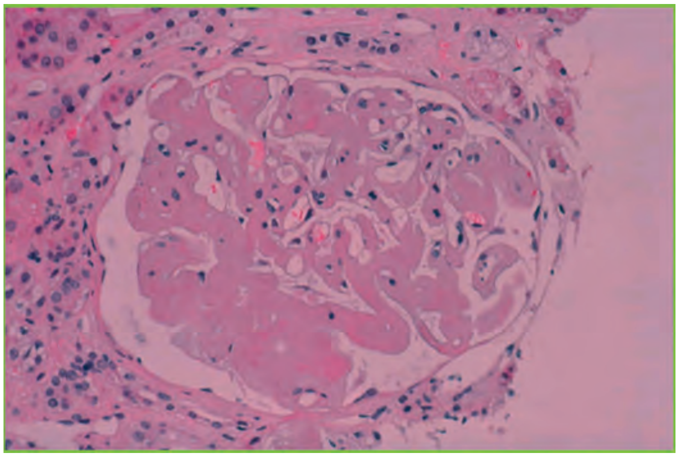

Figure 93.6 RENAL BIOPSY SHOWING AMORPHOUS HYALINE MATERIAL CONSISTENT WITH AMYLOID. (Original magnification, ×1000.)

Alternatively, if a patient with nephrotic range proteinuria has a monoclonal protein or an abnormal free light chain ratio, the diagnosis, which often includes minimal change glomerulopathy and membranoproliferative glomerulopathy, suddenly shifts to either (1) myeloma cast nephropathy, (2) immunoglobulin light-chain amyloidosis of the kidney (Fig. 93.6), or (3) κ light-chain deposition disease of the kidney (5% of patients may exhibit lambda deposition). In this situation, a kidney biopsy could be avoided by doing less invasive diagnostic testing.[16]

In a patient with fatigue, weight loss, or dyspnea upon exertion, the finding of an immunoglobulin abnormality raises the suspicion of amyloid. Evaluation can be redirected to include echocardiography with the specific inclusion of Doppler studies that accurately measure the restricted filling that occurs with amyloid infiltration (stiff heart syndrome). It may also include magnetic resonance imaging of the heart, which can show distinct endomyocardial enhancement following gadolinium injection, as well as myocardial nulling, which is specific for light-chain amyloidosis.[22] Myocardial nulling refers to an inversion recovery pulse sequence that is used to null the signal from the desired tissue to accentuate surrounding pathology. The nulled normal myocardium will be dark in contrast to the enhanced abnormal myocardium.

A patient with unexplained hepatomegaly who has a monoclonal protein can often avoid a liver biopsy, which can be associated with bleeding and occasionally with hepatic rupture. Fat aspiration or excisional fat biopsy is positive in over 75% of patients with hepatic amyloidosis. Minor salivary gland biopsy can demonstrate amyloid deposits in 68% of patients with amyloidosis and is more sensitive than a blind skin biopsy.[23] Salivary gland biopsy is complementary to fat pad biopsy in selected cases of negative fat pad biopsy, thereby avoiding liver, kidney, or endocardial biopsy.

In a patient with peripheral neuropathy who is found to have a monoclonal protein, consideration of amyloidosis in the differential diagnosis can prevent interventions such as plasma exchange or intravenous immunoglobulin infusions, which are ineffective in patients with light-chain amyloidosis but are often attempted in patients who have a monoclonal gammopathy and peripheral neuropathy (presumed CIDP) if amyloidosis is not considered in the differential diagnosis.[24] One needs to distinguish between IgM amyloidosis and IgM-mediated peripheral neuropathy, so-called DADS (distal acquired demyelinating symmetric neuropathy), a form of CIDP.

All patients with MGUS need to be monitored for life for the development of myeloma and AL amyloidosis. Over 25 years, approximately 25% of patients will go on to develop a more serious plasma cell dyscrasia. In 21%, this represents multiple myeloma, but 4% of patients with MGUS will develop light-chain amyloidosis during the course of observation. If screening is limited to detection of changes consistent with multiple myeloma, such as anemia, bone pain, and hypercalcemia, amyloidosis will be overlooked because all three of these findings are unusual in light-chain amyloidosis. Patient 2, as described above, was being followed by a hematologist for a monoclonal gammopathy, and when he developed fatigue (cardiac) in the absence of progressive anemia, amyloidosis was not considered.[25]

Any patient with one of the five compatible clinical syndromes listed in Table 93.1 should be screened for monoclonal protein. If a monoclonal protein is not found, the likelihood of light-chain amyloidosis is very small. However, if a monoclonal gammopathy exists with an appropriate clinical syndrome, histologic demonstration of the amyloid should be sought.

In patients who have renal, cardiac, hepatic, and peripheral nerve amyloid, the biopsy of the affected organs has a very high sensitivity of demonstrating the amyloid. However, these biopsies are not required if the amyloid is considered in the differential diagnosis.[26]

The first diagnostic studies that should be performed in patients with a compatible clinical syndrome and an immunoglobulin light-chain abnormality are a subcutaneous fat aspirate and a bone marrow biopsy. Subcutaneous fat aspirate in an experienced laboratory will demonstrate amyloid deposits in 75% of patients tested (Fig. 93.7). An excellent YouTube video has been produced by the Boston Medical Center on the technique (https://www.youtube.com/watch?v=tctYTmxd9gQ). In a patient with light-chain amyloidosis, staining of the bone marrow biopsy for amyloid deposition in blood vessels is positive 50% of the time. A second advantage of the bone marrow biopsy is it provides the percentage of plasma cells in the bone marrow, which is prognostic and is an essential evaluation in patients with immunoglobulin light-chain abnormalities. When combining the subcutaneous fat aspirate and the bone marrow biopsy, 85% of patients with light-chain amyloidosis will be identified. For the remaining 15%, a direct biopsy of the involved organ would be indicated if the index of suspicion for light-chain amyloidosis remained high. Other centers have reported success with biopsies of the minor submandibular salivary gland, skin biopsies, and endoscopic biopsies of the stomach. These procedures would be best undertaken in laboratories where there is extensive experience in the processing and staining of amyloid tissues.[27]

TABLE 93.1 **Syndromes in Primary Amyloidosis**

Syndrome	Patients (%)
Nephrotic or nephrotic and renal failure	30
Hepatomegaly	24
Congestive heart failure	22
Carpal tunnel	21
Neuropathy	17
Orthostatic hypotension	12

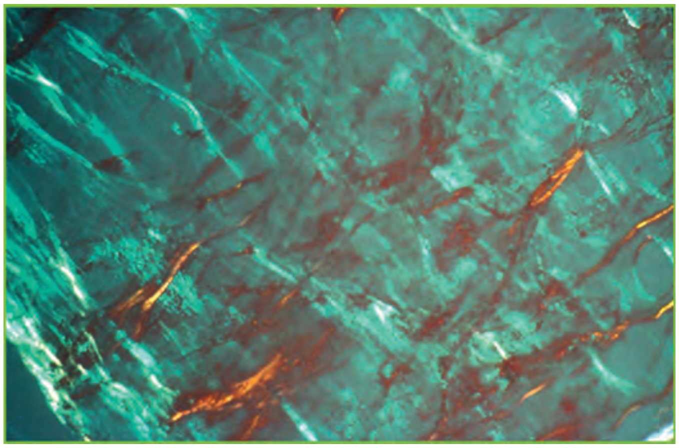

Figure 93.7 FAT ASPIRATION. (Congo red stain; original magnification, ×1000.) Note preserved fat cell interstices.

Once the amyloid has been demonstrated in histologic sections, it is imperative that the amyloid be typed to ensure it is of immunoglobulin light-chain origin because of the critical therapeutic implications. Although immunoglobulin light-chain amyloidosis is always associated with a monoclonal gammopathy, it is important to recognize that monoclonal gammopathies are common in the elderly population. On screening, 3% of adult patients over the age of 50 will have a monoclonal protein, and 5% of those over the age of 80 will have a monoclonal protein. Therefore, it is possible to have a positive biopsy for amyloid and a coincidental monoclonal protein when the amyloid itself is unrelated to immunoglobulin light-chain amyloidosis. Thus, when a pathologist reports amyloid-laden tissue, the task will not be complete until the specific protein subunit of amyloid is identified (Table 93.2). Historically, immunohistochemistry was used to classify amyloids. This technique is being used less. First, the type of amyloid can be identified only if the appropriate antibodies are used. In patients with amyloid deposition, it would be very challenging to diagnose dialysis-related amyloid (β_2-microglobulin type), insulin-type amyloid (found at the sites of insulin injection in diabetics), keratin amyloid (seen in skin biopsies), or TTR amyloid (seen in senile systemic amyloid, TTRwt). Most laboratories are not equipped with such a broad panel of antibodies. Second, even when light-chain amyloidosis exists, the use of anti-κ and anti-λ antibodies frequently will not be able to identify the type of amyloid in the tissue section. There are two widely held hypotheses for this lack of sensitivity of immunohistochemistry in AL amyloidosis.[28]

The first hypothesis is a reflection of the immunoglobulin in amyloid deposits. The light chain in amyloid is usually not the intact immunoglobulin light chain but usually represents a fragment. The average AL protein subunit is 12 kDa, approximately half the molecular weight of an intact immunoglobulin light chain. In most of these proteins, the constant portion of the light chain has been deleted.

TABLE 93.2 Nomenclature of Amyloidosis

Protein	Precursor	Clinical Characteristics
AL or AH	Immunoglobulin light or heavy chain	Primary or localized; myeloma or macroglobulinemia associated
AA	SAA	Secondary or familial Mediterranean fever, familial periodic fever syndromes
ATTR	Transthyretin	Familial and senile
A fibrinogen	Fibrinogen	Familial renal amyloidosis (Ostertag type)
$A\beta_2M$	β_2-Microglobulin	Dialysis associated; carpal tunnel syndrome
Aβ	ABPP	Alzheimer disease
A Apo A-I/A-II	Apolipoprotein A-I	Proteinuria
	Apolipoprotein A-II	Cardiac
		Neuropathy
A lysozyme	Lysozyme	GI tract
		Liver
		Renal
ALECT2	Renal	

AA, Amyloid A; *Aβ*, amyloid-β; *ABPP*, amyloid-β precursor protein; *$A\beta_2M$*, β_2-microglobulin-related amyloid; *AH*, amyloid heavy chain; *AL*, amyloid light chain; *ALECT2*, leukocyte chemotactic factor 2 amyloidosis; *Apo*, apolipoprotein; *ATTR*, transthyretin-related hereditary amyloidosis; *GI*, gastrointestinal; *SAA*, serum amyloid A.

BOX 93.1 Recommended Diagnostic Evaluation for Amyloidosis

- CBC
- Sodium, potassium, alkaline phosphatase, calcium, phosphorus, AST, bilirubin, creatinine, β_2-microglobulin, glucose, cholesterol, uric acid, thyroid profile
- Immunofixation; serum; immunofixation urine; nephelometric assay if immunoglobulin free light chains; immunoglobulins G, A, and M
- Troponin, NT-proBNP
- Factor X and prothrombin time
- Chest X-ray, EKG, echocardiogram with Doppler and strain imaging
- Cardiac MRI (optional selected situations)
- Bone marrow with FISH genetics, Congo red stain of marrow
- Fat aspiration

Most commercial antisera used in immunohistochemistry recognize the constant portion of the immunoglobulin light chain and, therefore, have no recognizable binding sites to AL, owing to the deletions it undergoes as it is deposited.[29]

The second hypothesis is that the immunoglobulin light chain, by definition, has undergone misfolding as it assumes the amyloid configuration in tissues. This misfolding can lead to the loss of available epitopes on the protein surface that commercial antisera bind to. It is for these reasons that it is common for immunohistochemistry, even in light-chain amyloidosis, to be equivocal or difficult to distinguish from background staining. At the Mayo Clinic, immunohistochemistry has been abandoned as a modality to diagnose the type of amyloidosis. Currently, laser capture microdissection with mass spectroscopic analysis of amyloid deposits has supplanted immunohistochemistry in our practice. Amyloid deposits can be excised by laser microdissection directly from a glass slide and then can undergo mass spectroscopic sequencing. The results are compared with a library of proteins stored in a database and then identified. Virtually all amyloid proteins contain serum amyloid P protein, apolipoprotein E, and vitronectin. These findings are confirmatory of the amyloid and serve as a good positive control but are ancillary proteins and are not the specific primary protein. In patients with amyloidosis, sequencing will identify the specific protein composition. In a survey of over 4000 tissues, light chains were detected by mass spectroscopic analysis in 61.68%, but 24.5% were transthyretin-related amyloidosis, 3.7% were amyloid A, 3.6% were leukocyte chemotactic factor 2 amyloidosis (ALECT2) (renal amyloidosis in Mexican and Indian patients), and insulin 1% (localized in diabetic). It is important to recognize that sites of subcutaneous insulin injection may form deposits of amyloid due to crystalline insulin. A subcutaneous fat aspiration at this site will demonstrate amyloid and mass spectroscopy is essential to distinguish localized insulin amyloid from a systemic form of amyloidosis., and the remaining comprised less than 1%. Due to its high sensitivity and specificity, mass spectroscopy is now our technique of choice.[30] The advantage of mass spectroscopic analysis is that it does not require any large panel of antibodies and can be done on fixed tissue on a glass slide. In addition, many commercial antibodies will not recognize the light chain immunoglobulin epitope either because of protein misfolding with loss of exposure or fragmentation of the immunoglobulin so that constant sequences are no longer present in the amyloid deposit.

In a survey of 143 heart biopsies, of which 81 were TTR (familial or senile systemic amyloid), an M protein was found in 20 patients, and free light chain abnormality was found in 8 of the 81 patients, indicating that the finding of an immunoglobulin protein does not prove that amyloidosis is AL in origin. Because senile systemic amyloidosis is a disease that causes heart failure in the elderly, the finding of a high prevalence of immunoglobulin abnormalities as a coincidental observation is not unusual.[31] Box 93.1 provides a list of the diagnostic tests needed to evaluate patients for whom amyloidosis is established as a diagnosis.

Other required diagnostic studies in patients with amyloidosis include cardiac biomarkers, which are extensively discussed in the section below on prognosis and screening measurements of the coagulation system. A unique and highly specific finding, albeit limited to no more than 5% of patients with light chain amyloidosis, is the development of deficiency of coagulation factor X. This is usually recognized as prolongation of the prothrombin time. The underlying mechanism of factor X deficiency in immunoglobulin light-chain amyloidosis is the direct binding of factor X to the amyloid deposit itself, which can occasionally be associated with serious clinical bleeding and can complicate the systemic therapy of this disorder. If a prothrombin time is completely normal, it is not our practice to routinely screen for factor X deficiency, but any abnormality of the prothrombin time or international normalized ratio should lead to a screening for factor X deficiency, given its unique association with light chain amyloid. In our experience, factor X deficiency is most commonly seen in patients with hepatosplenic deposits of AL amyloid.[32]

DIFFERENTIAL DIAGNOSIS

The path to the diagnosis of amyloid depends on the initial presentation. Many patients will be presented to a hematologist because of a monoclonal gammopathy and greater than 10% plasma cells in the bone marrow, which will fulfill the diagnostic criteria for myeloma, even though the clinical manifestations and the drivers of outcome could all be related to AL amyloidosis. It, therefore, is incumbent upon practicing hematologists who see a patient with smoldering multiple myeloma or MGUS to inquire about progressive fatigue out of proportion to any anemia, intractable edema, unexplained elevation of the serum alkaline phosphatase, unexplained weight loss, or the presence of peripheral neuropathy. The index of suspicion should be heightened if the monoclonal gammopathy is of λ type relative to κ type because of the stronger association with light chain amyloidosis. Any of these findings should lead to staining of the bone marrow biopsy for Congo red and the performance of subcutaneous fat aspiration. If the fatigue is significant, echocardiography, specifically to look for amyloid, and measurement of troponin and the N-terminal pro-brain natriuretic peptide (NT-proBNP) is indicated.[33] Conversely, any patient with a known nonischemic cardiomyopathy should be screened with serum and urine immunofixation and immunoglobulin light-chain assay because a positive result will redirect the evaluation toward AL amyloidosis. Any patient with albuminuria and a light chain should not be assumed to have myeloma cast nephropathy. Rather, the pattern of the urinary protein, whether albumin-dominant or globulin-dominant, can help distinguish between the two syndromes. In a patient with a peripheral neuropathy and a monoclonal protein, it should not be assumed that this is MGUS neuropathy; rather, screening for amyloidosis, in the presence of associated autonomic neuropathy (rare in MGUS neuropathy, 20% of AL amyloidosis) or concomitant carpal tunnel syndrome (50% of amyloid neuropathy patients, uncommon in MGUS neuropathy) is required. Congo red staining of tenosynovium tissue detected amyloid deposits in 10.2% of patients.[34] Six percent of patients with light chain amyloidosis have an IgM monoclonal protein. These patients' light chains are produced by lymphoplasmacytic cells in the bone marrow rather than plasma cells. This subtype of amyloidosis is characterized by a higher frequency of pulmonary involvement and a lower frequency of cardiac involvement. These patients also have a higher incidence of amyloid peripheral neuropathy. Therapy is directed at the lymphoplasmacytic clone rather than standard anti-plasma cell chemotherapy.

Other monoclonal immunoglobulin deposition diseases should be considered in the differential diagnosis. The most common would be light-chain deposition disease in the kidney where non-fibrillary granular deposits occur on the basement membrane of the glomerulus. Clinically, this manifests as a nephrotic syndrome that is hard to distinguish from renal amyloidosis. In most instances, renal biopsy is required.

Excluding Localized Amyloidosis

Localized forms of amyloidosis are characterized by the presence of amyloid deposits in biopsy tissue without systemic organ dysfunction. The typical sites associated with localized amyloidosis include skin, vocal cord, tracheobronchial tree, ureter, bladder, and urethra. Occasionally, GI biopsies, particularly polyps, or the edges of ulcers will show amyloid deposits and not be reflective of a systemic form of amyloidosis.[35]

In some instances, mass spectroscopic analysis will demonstrate that the amyloid is not of immunoglobulin light-chain origin. However, there are a number of forms of localized amyloidosis that are of immunoglobulin light-chain origin but are not part of a systemic plasma cell dyscrasia. When a deposit is seen and is of light-chain origin, but there is no evidence of a clonal plasma cell disorder in the bone marrow, and serum and urine immunofixation and light chain assays are normal, the index of suspicion should be that this is a localized form of amyloid for which systemic therapy is not indicated. Most forms of cutaneous amyloidosis do not require therapeutic intervention. Amyloidosis involving the vocal cords is most commonly treated by endoscopic resection of the deposits or yttrium-aluminum-garnet (YAG) laser vaporization of the deposits. Tracheobronchial amyloid deposits can be treated with laser vaporization of the deposits or, if the deposits extend beyond the reach of the bronchoscope, with external beam radiation, which has been reported to control the amyloid deposits successfully. Amyloids involving the ureter, bladder, and urethra often carry a preoperative diagnosis of urothelial malignancy. Surgeons have often treated patients with ureteral resections for suspected transitional cell carcinoma only to find that amyloid is present. Bladder amyloids most commonly manifest with gross hematuria, and endoscopic resection will demonstrate amyloid deposits. Most patients with localized bladder amyloid can be controlled via cystoscopic resection and then surveillance. There are occasional patients who require subtotal cystectomy. There is experience with the use of instillation of dimethyl sulfoxide into the urinary bladder. Urethral amyloid can usually be treated with resection to prevent obstruction.[36]

Systemic Forms of Amyloidosis Unrelated to Immunoglobulin Light Chain

The aging of the population is leading to increased recognition of TTRwt (senile systemic amyloidosis formally known as *senile cardiac amyloidosis*). Autopsy studies in patients over the age of 90 shows that nearly one-third of patients have cardiac amyloid deposits, and approximately half of those deposits were responsible for clinically significant cardiac dysfunction. With the rising age of the population and increased application of echocardiography, it is expected that the recognition of senile systemic amyloid, also known as *native TTR amyloid* or *wild-type TTR amyloid (TTRwt)*, will increase. Patients with this form of cardiac amyloidosis can develop congestive heart failure and commonly have conduction system abnormalities, including atrial fibrillation, first-degree heart block, and bundle branch block. The echocardiographic features are similar to those of light-chain amyloidosis, although extreme degrees of infiltration can be seen (septal thicknesses >20 mm), which are uncommon in light-chain amyloidosis. It should never be assumed that a patient with suspected cardiac amyloidosis has light-chain amyloidosis, particularly if the patient is over the age of 70. However, we have seen patients as young as 57 with TTRwt. Moreover, when patients are recognized by mass spectroscopy to have TTR cardiac amyloidosis, sequencing of the *TTR* gene is essential to exclude the possibility of a late-onset inherited form of amyloidosis. This is particularly the case because a specific mutation, ILE-122, is found in 4% of the African-American population in the United States and is associated with the development of late-onset cardiac amyloidosis, and we have seen patients with inherited cardiac amyloidosis who have been inappropriately treated with systemic chemotherapy. Technetium pyrophosphate (Tc-PYP) scanning can be diagnostic of transthyretin-related hereditary amyloidosis (ATTR) cardiac amyloidosis, both wild type and mutant.[37]

Familial amyloidosis represents a small but important subset of patients with systemic amyloidosis. The majority of cases are caused by mutations of TTR and can be recognized by identifying the TTR subunit by mass spectroscopy and detection of the mutation by sequencing of the *TTR* gene using polymerase chain reaction amplification techniques (Fig. 93.8). Clinically, most patients present either with cardiac amyloid or with amyloid peripheral neuropathy and are not easily distinguished clinically from immunoglobulin light-chain amyloid. Most of these patients will have no evidence of systemic plasma cell dyscrasia. Only half of the patients in our practice actually have a positive family history for this autosomal dominantly inherited disorder. In many instances, this is simply because of a failure to recognize in a prior generation and misattribution of the etiology of cardiac death or neural disability. Recognition of inherited TTR amyloidosis is important because there are now two approved gene silencers for inherited TTR neuropathy and one TTR stabilizer approved for TTR cardiomyopathy.[38]

There are forms of renal amyloidosis that are not immunoglobulin light chain in origin. The two most common are fibrinogen A α and ALECT2. Again, this requires mass spectroscopic identification of these subunit proteins to validate the diagnosis. The distinction of other forms of inherited amyloidosis is important. In TTR amyloidosis, multiple effective therapies have been US Food and Drug Administration (FDA) approved. In non-TTR inherited amyloidosis, organ transplant (renal transplant for apolipoprotein A1 amyloid renal failure) has been used for the management of renal and cardiac failure.[39]

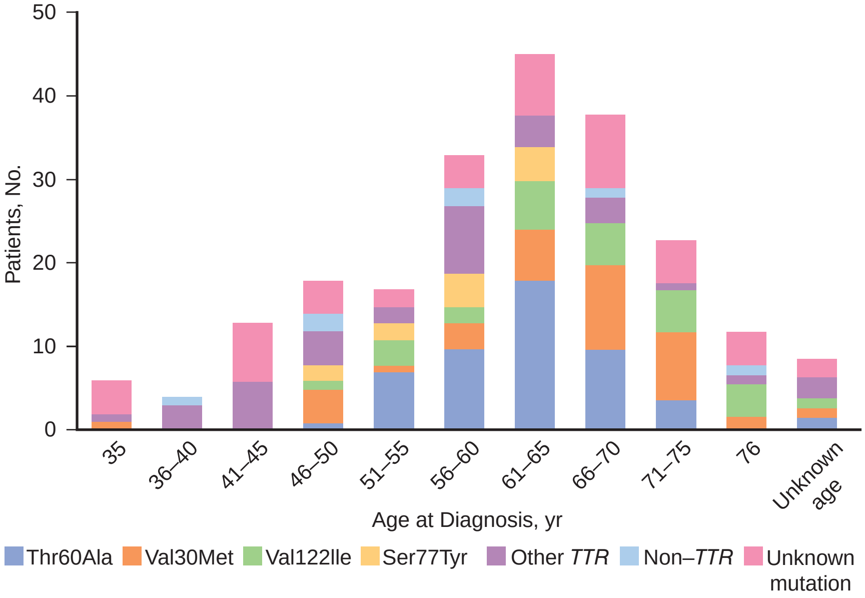

Figure 93.8 TRANSTHYRETIN MUTATIONS SEEN AT MAYO CLINIC, BY AGE. *TTR*, Transthyretin.

PROGNOSIS

The prognosis of immunoglobulin light-chain amyloidosis has been associated with abnormalities in lactate dehydrogenase, β_2-microglobulin, genetics, circulating plasma cells, the fraction of plasma cells in S-phase, and the serum amyloid P-scanning technique. The simplest and most powerful assessments of prognosis revolve around the importance of cardiac amyloid in determining the outcome.[40]

The most common cause of death in patients with cardiac amyloidosis is cardiac failure or sudden death, presumed to be caused by arrhythmia. However, the most common cause of death in renal, hepatic, and peripheral nerve amyloid is also cardiac amyloid. The presence of cardiac amyloid predicts for the fraction of patients unable to complete 3 months of therapy and remains responsible for the 1-year mortality of AL amyloidosis of 40%, which has not changed in 30 years, is the major driver of the outcome, and emphasizes why an earlier diagnosis of cardiac amyloid is essential to the improvement of outcomes for patients with this disease. In addition, the burden of plasma cells, as measured both in the bone marrow and by the levels of involved and uninvolved immunoglobulin light chains in the serum, is key in assessing prognosis. Box 93.2 gives the outcomes for the four stages of immunoglobulin light-chain amyloidosis, based on the measurement of cardiac troponin T, NT-proBNP, and the difference between the involved (iFLC) and uninvolved (dFLC) serum free light chain levels (see Box 93.2). These three blood tests have been converted into a very convenient staging system with dramatic differences in prognosis and almost equal distribution of patients into the four stages. Fig. 93.9 shows post-transplant overall survival for the four stages in 444 patients. Other important prognostic features, which are not currently part of the staging system, include echocardiographic Doppler studies of diastolic performance and mitral deceleration time (normal 140 to 240 ms). Echocardiographic strain at the apex, which measures the rate at which myocardial shortening occurs, has also been shown to be a powerful measure of outcome. Others have described a systolic blood pressure of less than 90 mmHg as being an adverse prognostic factor, but this has not been effectively incorporated into the current staging system for amyloidosis. At presentation, an NT-proBNP level greater than 8500 ng/L carries a particularly grave prognosis. A comparison of staging systems has been performed. The European model incorporating NT-proBNP of greater than 8500 has a better prediction for 1-year mortality. The Mayo staging system incorporating the free light chain increases the ability to predict long-term survival.[41,42]

BOX 93.2 Amyloid Staging

Patients are assigned a score of 1 point for each of the following:

1. FLC-diff ≥18 mg/dL
2. High sensitivity cTnT ≥40 ng/L
3. NT-proBNP ≥1800 pg/mL

This creates stages I–IV with scores of 0–3 points, respectively

Median survival (months):

I. 94.1
II. 40.3
III. 14
IV. 5.8

cTnT, Cardiac troponin T; *FLC-diff*, difference between involved and uninvolved serum free light chains; *NT-proBNP*, N-terminal pro-brain natriuretic peptide.

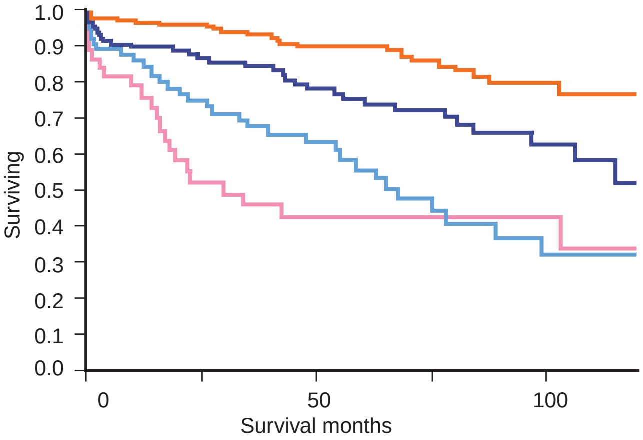

Figure 93.9 SURVIVAL BY STAGE FOLLOWING STEM CELL TRANSPLANT. *Orange*, stage I; *dark blue*, stage II; *light blue*, stage III; *pink*, stage IV.

Patients who present with an involved free light chain of less than 5 milligram/deciliter have an inherently better prognosis and longer survival than those who present with an involved free light chain level greater than 10. The optimal response is assessed by the difference between the involved and uninvolved light chain and is superior to using the light chain ratio. We believe the involved free light chain should be reduced as low as possible, preferably to less than 2 mg/dL which is associated with a higher organ response rate and improved progression-free and overall survival[43]).

Response Assessments and Importance of Supportive Care in Amyloid Light-Chain Amyloidosis

Before one can understand the various therapies, it is important to understand how to interpret response in patients with amyloidosis. In amyloidosis, because there is both a plasma cell dyscrasia and organ dysfunction related to amyloidosis, there are now response criteria for both hematologic and organ responses. Hematologic responses parallel response criteria that have been established for multiple myeloma and rely heavily on the measurement of the involved and uninvolved immunoglobulin free light chain.[44]

The immunoglobulin free light chain assay has been summarized earlier as being critical in the recognition of the disease; it has been described as being important in prognosis, and its serial measurement is the key to assessing hematologic response. In fact, when both an intact immunoglobulin is present and an abnormal involved free light chain is detected, the latter is more important prognostically than changes in the intact immunoglobulin and the light chain value is given preference to intact immunoglobulin levels when interpreting responses in treated patients and for assessment of the role of salvage therapies. A complete hematologic response is defined as a negative serum and urine immunofixation, a normal free light chain ratio, and a normal bone marrow examination. A very good partial response is now defined as a difference between involved and uninvolved free light chain of less than 40 mg/L. A partial response is a 50% reduction in the difference between involved and uninvolved serum free light chain levels, and less than a 50% decrease is considered a stable disease. A cardiac response in amyloidosis is defined not by changes in the echocardiogram but by changes in the NT-proBNP. A decrease of NT-proBNP of 30% and at least 300 ng/L is considered a response. However, the NT-proBNP level must be greater than 650 ng/L prior to therapy to be considered measurable for cardiac organ response. The definition of renal response is a 50% reduction in the amount of urinary protein loss over a 24-hour period. This reduction is associated with longer survival. A 75% reduction in proteinuria is associated with markedly prolonged survival.[45]

The therapy for amyloidosis is both supportive care and systemic chemotherapy against the plasma cell dyscrasia. Supportive care for cardiac and renal amyloidosis includes diuretic therapy to help reduce the elevated filling pressures in both the right and left sides of the heart and reduce pulmonary edema, as well as to relieve symptomatic lower extremity edema. Diuretics are also required for the management of the lower extremity edema associated with nephrotic syndrome. Many cardiologists at the Mayo Clinic believe that torsemide is a superior diuretic to furosemide in patients with amyloidosis. For refractory edema, the addition of metolazone can be useful, but it can result in serious hypokalemia when combined with furosemide or torsemide. There is no evidence that the use of lisinopril, as has been applied in the nephrotic syndrome of diabetic nephropathy, plays any role in the management of renal amyloidosis. In addition, afterload reduction, shown to provide a survival benefit in patients with ischemic cardiomyopathy, has not been shown to be beneficial in patients with amyloidosis and can significantly aggravate hypotension in patients with poor filling during diastole. Finally, a number of patients in our practice have shown significant deterioration with the addition of β-blockade, and these agents are avoided in our patients as well. For cardiac AL amyloidosis, an implantable cardiac defibrillator (ICD) has been reported in 15 patients. The median time to implantation was 13 days from the first presentation. Thirteen of the 15 received oral amiodarone after implantation. One patient had ventricular fibrillation after 8 days and was successfully reverted to sinus rhythm but died 10 days later with intractable ventricular fibrillation. Only two of the four patients achieved longer-term survival with an ICD.[46,47]

The arthropathy of amyloidosis can be challenging but most patients benefit from low doses of prednisone such as 10 mg daily. Amyloid neuropathy can be managed with gabapentin, pregabalin and scrambler therapy. In scrambler therapy, electrocardiographic-like pads are placed around the area of pain. The device then synthesizes different types of nerve action potentials that deliver nonpain information through cutaneous nerves to the pain site.

Management of amyloid orthostatic hypotension involves the use of both fludrocortisone and midodrine, which can help reduce orthostatic syncope but are associated with both fluid retention and supine hypertension, making their use a challenge. The diarrhea associated with GI amyloid is also challenging. It is common for these patients to fail imodium therapy and loperamide. We frequently will use tincture of opium to manage this situation. In refractory instances where fecal incontinence is common, the placement of a diverting sigmoid colostomy has no impact on the diarrhea but can provide the patient important improvement in quality of life and social relief.[48]

Treatment for Light-Chain Amyloidosis

The treatment of light-chain amyloidosis requires a determination of whether the patient is a candidate for high-dose therapy with a stem cell transplant or is best served with conventional regimens.[49]

It is now 40 years since melphalan and prednisone treatment was shown to benefit patients with AL amyloidosis, and two randomized clinical trials comparing melphalan and prednisone with colchicine regimens demonstrated a response rate of 15% and a 50% increase in median survival in responders. Melphalan has a significant impact on survival in patients without heart failure. The best responses to melphalan-containing regimens are in patients with renal amyloid nephrotic syndrome and preserved renal function.[50]

Dexamethasone in high doses of 40 mg on days 1 to 4, 9 to 12, and 17 to 20 as demonstrated in three individual studies to result in organ improvement in amyloid patients for whom melphalan-containing regimens had failed. Subsequently, the combination of melphalan and weekly dexamethasone was introduced, showing a 50% 5-year survival rate, a hematologic complete response rate of 24%, and organ improvement of 43% (Table 93.3). Oral melphalan and dexamethasone can be administered to virtually any patient with AL amyloidosis and should be considered the standard with which all other therapies are compared. There is a strong correlation between organ improvement and hematologic response. In patients who achieve a hematologic complete response, organ improvement has been seen in 87% of patients. Organ response rates are less than 15% in the patients who do not achieve a hematologic partial response. Bendamustine, an agent with alkylating type properties, was studied in 122 patients. In this relapsed population the

TABLE 93.3 Current Regimens for Light-Chain Amyloidosis Therapy

Melphalan dexamethasone	50% response rate can be used with renal and cardiac failure
Cyclophosphamide bortezomib dexamethasone	Most common triplet regimen in use
Daratumumab cyclophosphamide bortezomib dexamethasone	Appears to triple the ≥VGPRrate in newly diagnosed patients with NT-proBNP <8500 ng/mL
Bortezomib lenalidomide dexamethasone	Lenalidomide poorly tolerated; aggravates cardiac congestion; initial lenalidomide dose 5–10 mg
Pomalidomide	Active second line regimen. Caution with cardiac amyloidosis
Venetoclax	Potential when t(11;14) present

NT-proBNP, N-terminal pro-B-type natriuretic peptide.

overall hematologic response rate was 35%. Median survival was 48 months but was significantly longer for IgM amyloidosis and represents ineffective salvage therapy.[51]

The introduction of proteasome inhibitors and immunomodulatory agents has broadened the horizon for patients with AL amyloidosis. Initial experience with thalidomide demonstrated that the administration of immunomodulatory drugs to patients with amyloidosis cannot be implemented solely on the basis of experience with multiple myeloma. In an early study of 16 patients with AL amyloidosis treated with thalidomide, grade 3 or greater adverse events were noticed in 50% of patients, including exacerbation of neuropathy and heart failure. When thalidomide was combined with cyclophosphamide and dexamethasone, the hematologic response rates were high, but the toxicity was significant.[52]

Lenalidomide has demonstrated activity in AL as a single agent and combination with steroids and the alkylating agents, cyclophosphamide and melphalan. Lenalidomide appears to be better tolerated than thalidomide but produces significant increases in the NT-proBNP and symptomatic exacerbations of cardiac symptoms. In a phase II trial of 35 patients, 8 of 13 evaluable subjects had a hematologic response, but the maximum tolerated dose of lenalidomide was only 15 mg. Lenalidomide has been used as salvage therapy in patients who have progressed after melphalan, dexamethasone, and bortezomib combinations. Melphalan, lenalidomide, and dexamethasone in a relapsed setting produced hematologic complete response rates in 42% of patients. A phase II trial at the Mayo Clinic of cyclophosphamide, lenalidomide, and dexamethasone also produced response rates of 50%, with 7% showing a complete response. Myelosuppression with the combination of melphalan and lenalidomide is significant. Cardiac arrhythmias were seen in 33%.[53]

As a salvage therapy in relapsing disease, lenalidomide has been combined with cyclophosphamide and dexamethasone in 35 patients. The median number of treatment cycles was six, and the hematologic response rate was 60%; in those receiving at least four cycles, the response rate was 87%. A median overall survival of 37.8 months has been reported. In patients with amyloidosis, lenalidomide has been reported to worsen renal function even in patients whose amyloidosis spares the kidney. Recovery of renal function was reported in 44%. Lenalidomide salvage therapy after bortezomib achieves a hematologic response rate of 41%. Pomalidomide is a third-generation immunomodulatory drug with a toxicity profile that compares favorably with the other immunomodulatory drugs. In a single phase II trial, 29 patients previously treated received pomalidomide with a response rate of 38%. Seventy-five percent of patients were alive at 1-year, and 56% were free of progression. The majority of these patients had previously received stem cell transplants, bortezomib, and thalidomide, indicating that this immunomodulatory drug is active and capable of producing durable remissions, albeit with significant toxicity. Twenty-nine patients were treated with pomalidomide at the National Amyloidosis Centre in the United Kingdom. Thirty-five percent of patients achieved a very good partial response, in 31% a partial response. Median overall survival was 27 months; median progression-free survival was 15 months. Pomalidomide represents an effective second-line therapy for AL amyloidosis. The quality of responses in the second-line is in large part predicted by the quality of response to first-line therapy.[54]

Bortezomib

Bortezomib, which was the first proteasome inhibitor used for the treatment of amyloidosis, has the advantage of a rapid time to response and no modification required for renal dysfunction. In the first phase II trial, 14 of 18 patients with relapsed refractory AL amyloidosis had a hematologic response, with 16% achieving complete response. Schedules of weekly and twice-weekly bortezomib have been investigated with similar response rates and similar 1-year progression-free survival. The weekly use of bortezomib, however, does appear to have lower rates of treatment discontinuation and peripheral neuropathy. Bortezomib has been combined with dexamethasone with a hematologic response rate of 71%, complete in 25%. In previously untreated patients, bortezomib produces a complete response rate of 47%, although in one study the progression-free survival was only 5 months and the overall survival was 18.7 months, raising questions about how durable these responses are. Bortezomib has also been combined with stem cell transplant as induction therapy, as a post-transplant consolidation therapy, and as a part of the conditioning regimen. In a report of 19 patients for whom bortezomib was used after stem cell transplant to deepen the response, 67% of patients achieved a complete response, with organ responses in 60% using post-transplant consolidation with bortezomib. Data from 33 national centers were combined, with 94 patients having received bortezomib. A cardiac response was seen in 29% of patients. The NT-proBNP predicted survival. The median time to response was 7.5 weeks. Authors of a survey of European centers with 428 evaluable patients reported that bortezomib therapy achieved a lower difference between involved and uninvolved free light chains at the end of therapy compared with cyclophosphamide-thalidomide-dexamethasone, melphalan-dexamethasone, stem cell transplant, and cyclophosphamide-lenalidomide-dexamethasone.[55]

Bortezomib had been combined with cyclophosphamide and dexamethasone. In a study of 17 patients, 10 of whom were therapy-naive, a response rate of 94% was achieved, 71% complete. A second cohort of 43 patients achieved a hematologic response rate of 81%, with 42% achieving a complete response and a 2-year progression-free survival of 67% for newly diagnosed patients.[56]

Despite the promising published results with bortezomib, a prospective randomized trial conducted in Europe of bortezomib, melphalan, and dexamethasone (BMD) compared with melphalan and dexamethasone failed to show any difference in organ response rates or in progression-free or overall survival in the bortezomib-containing regimen; yet grade 3 toxicity was seen in 27% of patients receiving BMD compared with only 12% treated with melphalan and dexamethasone. Moreover, day 100 all-cause mortality was 7.5% in the BMD arm and only 2.5% in the melphalan–dexamethasone arm. The hematologic response rate was higher in the BMD arm at 77% versus 52% ($P = .045$). A compilation of 230 patients in Europe who received cyclophosphamide, bortezomib, and dexamethasone showed a high level of effectiveness in low-risk amyloidosis patients with an at least very good partial response rate of 56% and no deaths seen in stage I patients. In a trial of 915 patients treated with bortezomib, the overall response rate (intent-to-treat) was 65%, with 49% complete response (CR)/very good partial response/low dFLC response and with a stringent dFLC response, dFLC 10–40 mg/L, and dFLC greater than 40 mg/L was 30%, 22%, and 48%, respectively. Median overall survival was 72 months.[57]

A European collaborative study of treatment outcomes in 346 patients with cardiac stage III AL amyloidosis was reported. In this cohort of patients with advanced cardiac amyloidosis, the median overall survival was 7 months with a 2-year overall survival of 29%. As is typical for this disease, 42% of patients died before their first response evaluation, and the overall hematologic response rate was 33% (12% complete). The overall survival rate was 88% at 2 years for complete responders, 53% for partial responders, and 22% for nonresponders; 45% of responders achieved an organ response. The only factors predictive of survival were an NT-proBNP >8500 ng/L and a systolic blood pressure less than 100 mmHg. The regimens administered included melphalan and dexamethasone, alkylating agents, thalidomide and dexamethasone, and bortezomib as well as lenalidomide combinations. Although this was not a prospective trial, the overall response rate for melphalan–dexamethasone–thalidomide–bortezomib combinations ranged from 60% to 64%. The response rate to lenalidomide combination therapy was 41% but included only 13 patients. The most common regimen administered was melphalan and dexamethasone, administered to 154 of the 286 patients evaluable for response.[58]

Carfilzomib has been used particularly in the treatment of light-chain amyloid neuropathy. However in view of the very high incidence of cardiac involvement with amyloidosis and toxicity of carfilzomib to cause hypertension and dyspnea its use has been limited due to toxicity.

Daratumumab

Daratumumab is an anti-CD 38 monoclonal antibody with an established role as monotherapy in multiple myeloma. Daratumumab as a single agent in relapsed refractory amyloidosis has provided impressive preliminary results. Among five case series published on 142 patients the median time to response ranges from 1 to 2.2 months and the overall response rate ranged from 63 to 100%. The response depth greater than or equal to very good partial responders range from 46 to 86%. In a series reported from Mayo Clinic, the median follow-up was 10.2 months the complete response rate was 17% and the median time response was 2.2 months. This is a highly active agent and a phase III trial that is completed accrual has compared daratumumab-cyclophosphamide-bortezomib-dexamethasone to cyclophosphamide-bortezomib-dexamethasone. In the final publication daratumumab increased the complete response rate 3-fold and doubled both the renal and cardiac organ response rates. Daratumumab is the only FDA-approved agent for the treatment of AL amyloidosis. The combination of daratumumab, cyclophosphamide, bortezomib, and dexamethasone is now considered the standard of care for newly diagnosed patients with AL amyloidosis.[59,60]

Autologous Hematopoietic Stem Cell Transplantation

Unlike multiple myeloma, where visceral organ function tends to be normal with the exception of the kidney, and the bone marrow tends to be heavily involved, the converse is true in AL amyloidosis. In amyloidosis, the marrow usually shows minimal involvement, but organ dysfunction increases the morbidity as well as the mortality of high-dose chemotherapy and stem cell transplant. Ablative therapy can be more effective, and the response durability of patients who achieve a complete response is greater in AL amyloidosis than it is in multiple myeloma, the number one indication for autologous stem cell transplant in the United States. Stem cell transplant is not a suitable technique for patients with advanced cardiac disease, because these patients decompensate if they develop neutropenic infection during the phase of maximal myelosuppression. Careful patient selection becomes critical in ensuring a safe outcome for patients who undergo stem cell transplants. Over the past two decades, the treatment-related mortality associated with stem cell transplants has fallen from 10% to 2% because of improved supportive care and optimization of patient selection. As a general guideline, it has been our experience that patients whose systolic BP is less than 90 mmHg or whose troponin T is greater than 70 ng/L at diagnosis have too high a mortality associated with transplant and are better managed with standard-dosage chemotherapy, as outlined in the previous section. Systolic blood pressure less than 90 mmHg reflects insufficient diastolic compliance to improve cardiac output during the stress of stem cell transplant. Patients who have stage III and stage IV cardiac amyloidosis are candidates for stem cell transplant if they fulfill the other criteria outlined. Reports from the Boston University Medical Center performing stem cell transplantation in patients who had significant elevation of cardiac biomarkers (NT-proBNP >5000) demonstrated a treatment-related mortality of only 5% despite advanced cardiac involvement.[61]

At the Mayo Clinic, approximately 20% of patients with newly diagnosed amyloidosis are eligible for high-dose melphalan. Melphalan 200 mg/m^2 and 140 mg/m^2 can both be used, but the response rates associated with lower-dose melphalan are decreased and may not be superior to the response rates reported with standard chemotherapies. The ability of stem cell transplant to produce a durable response is unmatched in the literature, with 43% of patients surviving 10 years or longer. Patients with more than two organs involved are oftentimes not considered adequate candidates for stem cell transplant, but some judgment is warranted because patients can have very mild involvement of three organs and be candidates, yet have advanced involvement of two organs and not be candidates (Fig. 93.10). The serum creatinine is predictive of the risk of requiring dialysis during the transplant, a major complication leading to serious morbidity. We are disinclined to perform the transplant in renal amyloid patients whose serum creatinine is ≥2.0 mg/dL. Although age is not an absolute criterion, additional scrutiny is warranted above the age of 65. From January 1, 2013, through December 31, 2014, 85 amyloid patients underwent transplants; 35 were older than 65 years of age, and 11 were over age 70 years.[62] Median overall survival for the entire cohort was 122 months. Treatment-related mortality declined over time to 2.4%. When careful selection is applied, these results are comparable to younger patients

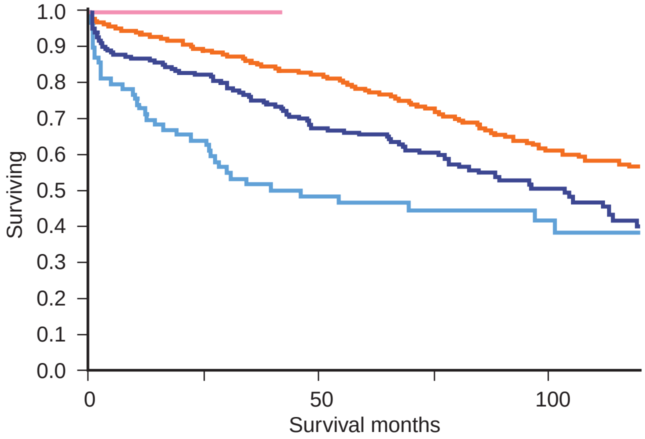

Figure 93.10 SURVIVAL AFTER STEM CELL TRANSPLANT, BASED ON NUMBER OF ORGANS INVOLVED. *Pink*, Soft tissue only, no visceral involvement; *orange*, 1 organ; *dark blue*, 2 organs; *light blue*, >2 organs.

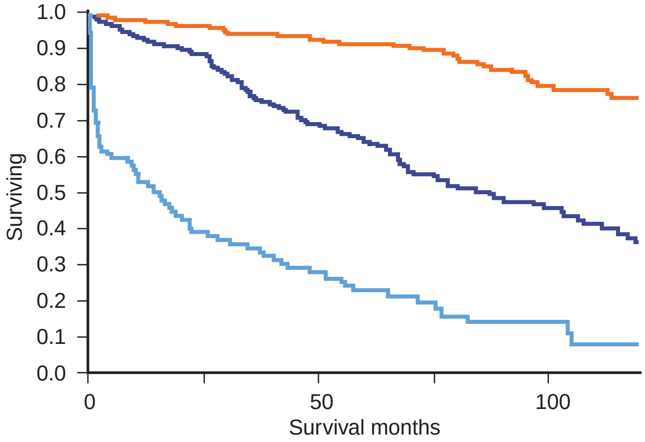

Figure 93.11 SURVIVAL BY RESPONSE DEPTH. *Orange*, Complete response; *dark blue*, partial response; *light blue*, no response.

As with conventional chemotherapy, hematologic response is a predictor of survival, with complete responders having improved outcomes compared with very good partial responders and partial responders (Fig. 93.11). The depth of the hematologic response required to achieve optimal outcomes is not well defined in amyloidosis, because highly amyloidogenic light chains can continue to deposit even if the levels are sharply reduced. Unlike myeloma (where the monoclonal protein is a surrogate for tumor mass), in amyloidosis, the monoclonal protein is itself the problem, and to completely disrupt deposition, one may hypothesize that nearly complete eradication of the protein from the serum is required. In amyloidosis, hematologic response is used as a surrogate for organ response, which is the only outcome that improves survival by the prevention of progressive organ failure.[63]

Most published information on high-dose therapy and stem cell transplant in amyloidosis have used melphalan in doses ranging from 100 to 200 mg/m^2 as the standard. The Boston Medical Center reported 250 patients with AL amyloidosis who underwent high-dose melphalan and autologous stem cell rescue. Two-thirds were alive at a mean follow-up of 23 months, with a 3-month all-cause mortality of 14%. Febrile neutropenia, GI tract hemorrhage, and dialysis-dependent renal failure were unique toxicities associated with transplants. However, the Boston group has demonstrated an improved quality of life for patients who respond. We have published our experience with

434 patients with amyloidosis. The hematologic response rate among those patients was 75%. The complete response rate was 38%, and the organ response rate was 46%. The most important predictor of outcome was the depth of hematologic response. Median survival was not reached for patients who achieved a complete response, whereas it was 107 months for those with partial remission and 32 months for nonresponders (Fig. 93.11). There is a significant impact of pretreatment NT-proBNP levels on outcome. We do not use chemo-mobilization to obtain stem cells. The low number of plasma cells in the bone marrow allows growth factor-only mobilization to achieve the requisite goal. Stem cell mobilization (SCM) is associated with unusual morbidity in AL amyloidosis compared to multiple myeloma, even when performed without chemotherapy. In a large monocentric series, 11% of patients SCM with granulocyte colony-stimulating factor (G-CSF) did not proceed to stem cell transplantation due to complications and 4% died during SCM. Caution must be exercised when selecting patients with AL amyloidosis for stem cell mobilization. Extreme caution must be used in patients that are not fit. Hypoxia and hypotension are rare life-threatening events during SCM with G-CSF and may be the result of a capillary leak syndrome triggered by the growth factor. Plerixafor is not routinely used to mobilize stem cells; it is used only in patients who do not achieve a peripheral blood CD34 count greater than 10/μL. We also do not routinely use granulocyte colony-stimulating factor to support engraftment following transplant, owing to fluid retention that is seen, and we have observed no increase in bacteremia or hospital days after ceasing use of post-transplant growth factor support. Among AL amyloid patients, approximately 30% will complete the procedure without requiring hospitalization. Adjuvant therapy has been used in patients who are the recipients of stem cell transplants. Both thalidomide–dexamethasone and bortezomib–dexamethasone has been used to consolidate a response after transplant, and it has been demonstrated that the deepening of the response can be achieved.[64]

It is difficult to obtain category A evidence in support of high-dose therapy and stem cell transplant for AL amyloidosis. The only prospective controlled trial enrolled 100 patients and did not demonstrate survival differences between the two groups, whether in a landmark analysis or on an intention-to-treat basis. This study has been called into question because of a 24% treatment-related mortality in the transplant group. A subsequent meta-analysis of high-dose therapy in patients with AL amyloidosis also could not identify a survival advantage with stem cell transplant. Boston University has reported a 10-year survival of 25% in their transplant population, compared with 4% prior to the advent of high-dose therapy. A case-matched control study done at the Mayo Clinic matched 63 transplanted patients with 63 non-transplanted patients and showed a survival advantage for patients who received a stem cell transplant. A retrospective comparison of stem cell transplantation with chemotherapy alone was performed in 232 patients. The median event-free and overall survivals were significantly better in the transplant group than in the chemotherapy group even when patients with severe findings were excluded. The hazard ratio for event-free survival was 0.41 and for overall survival was 0.31.[65]

In a report from MD Anderson, including 128 patients that received high-dose therapy, induction therapy within immunomodulatory drug or proteasome inhibitor was associated with better overall survival and was safe and feasible. The 2-year progression-free survival with combination chemotherapy induction was 73%. In a report from Mayo Clinic Arizona, 63 patients underwent stem cell transplants, and 34 received bortezomib-based therapy before transplant. Bortezomib-based induction resulted in improved hematologic response organ response and overall survival.[66]

MAYO CLINIC TREATMENT APPROACH IN NEWLY DIAGNOSED AMYLOID LIGHT-CHAIN AMYLOIDOSIS

Organ Transplantation

Both cardiac and renal transplants have been performed in patients with AL amyloidosis. Criteria to be considered in selecting patients for solid organ transplant include amyloidosis confined only to the organ that is to be transplanted. Also, the patient should either have achieved a complete hematologic response with therapy or be a candidate for therapy that has a high likelihood of producing a complete hematologic response and thereby obviate the possibility of recurrent amyloid in the transplanted organ.[67]

Three patients were reported with AL amyloidosis who had cardiac involvement, and the time from symptomatic onset to the diagnosis of AL amyloidosis ranged from 12 to 24 months. The times from the onset of heart failure to orthotopic heart transplant in these three patients were 4, 5, and 7 months, respectively. The patients then underwent a stem cell transplant at 13, 16, and 13 months, respectively; all three are alive at 23+, 35+, and 39 months, demonstrating that in highly selected patients, heart transplants in those with dominant cardiac involvement followed by subsequent stem cell transplant can result in survival benefit. The authors of a report of six patients who underwent a heart transplant for cardiac amyloidosis at Stanford stated that all patients received chemotherapy in the interval between heart transplant and autologous stem cell transplant. Five patients were alive up to 25 months after heart transplant without evidence of recurrent cardiac amyloid deposition, but chemotherapy began as early as 32 days after the cardiac transplant. The three patients are alive 19, 24, and 25 months post-transplant, respectively.[68,69]

Renal transplant has also been reported. Nineteen patients with AL underwent renal transplant, comprising living donor transplants in eighteen and a cadaveric transplant in one, with a median follow-up of 41.4 months; 79% were alive, and five patients had cellular rejection. Recurrent amyloidosis was diagnosed by a kidney biopsy in only one patient, indicating that renal transplant can be successfully performed in patients with AL amyloidosis in complete hematologic response without a significant risk of recurrent amyloid when the primary hematologic disorder is controlled. A recent report noted a median overall survival of 10.5 years from renal transplantation and a 5-year graft survival of 81%. Patients with a complete your very good partial response to therapy had significant overall survival from diagnosis and a lower rate of recurrence of amyloidosis in the graft. During a median follow-up of over 7 years, no lymphoproliferative disorder or second cancer developed. In this cohort, renal transplantation occurred at a median of 2.4 years after hematologic response and was considered reasonable to proceed with renal transplantation when hematologic response was present of at least 6 to 12 months.[70]

Nine cardiac transplants were reported from Boston, eight of whom subsequently received a stem cell transplant. Six of seven evaluable patients achieved a complete hematologic remission. One achieved a partial remission. At a median follow-up of 56 months, five of seven patients were alive without recurrent amyloid, comparable to patients who received heart transplants for non-amyloid heart disease. At the Mayo Clinic, the 5-year survival of patients who have received cardiac transplants for amyloid is inferior to patients who receive hearts for cardiomyopathy without a systemic disorder. Eleven patients underwent heart transplants followed by autologous peripheral blood stem cell transplant. Two patients died as a result of transplant-related complications. Nine survived, but three died because of progressive amyloidosis. The 1- and 5-year survival rates were 82% and 65%, respectively. The median survival was 76 months from a heart transplant and 57 months from stem cell transplant. A report on 32 patients with AL cardiac amyloidosis reported a significantly lower survival than patients with non-amyloid cardiomyopathy after heart transplantation. Outcomes improved substantially in the bortezomib era. The 2-year survival was 80%.[71]

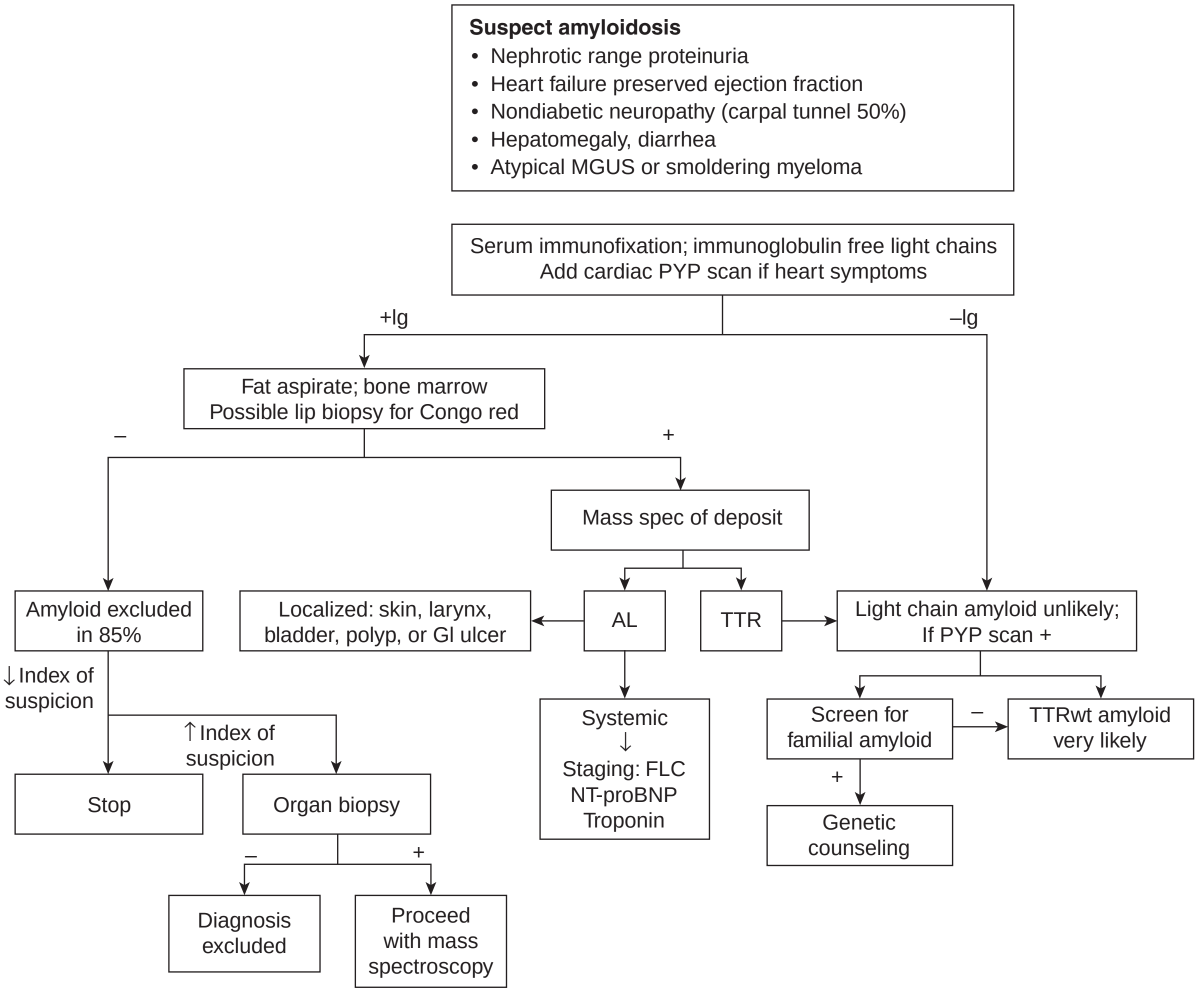
Organ transplant is a viable option for patients in whom complete suppression of light chain production can be achieved. Because of the shortage of organs, critical decisions regarding allocation must be made. Organ transplant has also been applied to familial amyloid polyneuropathy amyloidosis, usually combined with liver transplant. We have performed three cardiac transplants for familial amyloidosis, heart transplantation for TTRwt amyloid in 2 patients, heart–liver transplant for familial amyloid in 18 patients, and heart–liver–kidney transplant for familial amyloid in 4 patients.[72]

In general, organ transplantation should not be considered unless the underlying plasma cell clone can be well controlled to prevent recurrent deposition into the transplanted organ. Virtually all recipients have single organ involvement. It would not be appropriate to do renal transplantation in a patient with advanced cardiac amyloidosis. In patients with cardiac amyloidosis, the heart failure is usually too severe to sustain intensive chemotherapy. These patients receive an organ and then are aggressively managed to suppress the plasma cell clone after approximately 6 months posttransplant.

> A 44-year-old male was found to have nephrotic range proteinuria. A renal biopsy was performed and the patient developed a massive hematoma that required surgical evacuation. Postoperatively, there was oozing from the incision site. The renal biopsy demonstrated amyloidosis and mass spectroscopic analysis revealed lambda type. The patient's INR was 2.4 and the partial thromboplastin time (PTT) was 85 seconds. Specialized coagulation studies demonstrated factor X level of 8%. The patient received 4 months of bortezomib–cyclophosphamide–dexamethasone with no change in the factor X level despite normalization of elevated free light chains. The patient was taken to autologous stem cell transplant. Factor X levels were maintained by the use of factor X concentrate daily through the thrombocytopenic period. By day 100, factor X was 35% and the PTT and INR were both normal.

CONCLUSIONS

Amyloidosis should always be considered in the differential diagnosis of a patient who presents with proteinuria and is nondiabetic. Any patient with unexplained fatigue or restrictive cardiomyopathy or heart failure with preserved ejection fraction should be screened for amyloidosis. Patients who fulfill criteria for chronic inflammatory demyelinating peripheral neuropathy, unexplained hepatomegaly, or atypical multiple myeloma should all be considered for the possibility of amyloidosis. When a patient with one of these five compatible syndromes is seen, screening with immunofixation of the serum or urine in a free light chain assay should be performed (Fig. 93.12). If an immunoglobulin light-chain abnormality is found, it would be appropriate to do biopsies of the bone marrow and subcutaneous fat to stain for Congo red. Only if the index of suspicion is high should further biopsies be performed if the results of bone marrow and fat biopsies are both negative. It is critical to ensure that all amyloid deposits are typed. The gold standard is laser capture mass spectroscopy in an effort to ensure that all chemotherapy-treated amyloid is of immunoglobulin light-chain origin. The prognosis of amyloidosis can be determined by measurements of the immunoglobulin free light chain, serum troponin, and NT-proBNP. We believe that stem cell transplant is the preferred technique for patients in whom it can be performed safely, but this should not be more than 20% of patients. For non-transplant candidates, melphalan–dexamethasone, melphalan–dexamethasone–bortezomib, and cyclophosphamide–bortezomib–dexamethasone are all legitimate options for induction



Suspect amyloidosis
• Nephrotic range proteinuria
• Heart failure preserved ejection fraction
• Nondiabetic neuropathy (carpal tunnel 50%)
• Hepatomegaly, diarrhea
• Atypical MGUS or smoldering myeloma
Serum immunofixation; immunoglobulin free light chains
Add cardiac PYP scan if heart symptoms

therapy. For patients without a response to their primary therapy, immunomodulatory drug-containing therapies such as melphalan–dexamethasone–lenalidomide, lenalidomide–dexamethasone, and cyclophosphamide–lenalidomide–dexamethasone are all appropriate combinations.[53]

FUTURE DIRECTIONS

Some of the research-based initiatives for amyloidosis treatment are listed in Table 93.4. Antibodies, small interfering RNA, and antisense oligonucleotides are all being explored in TTR amyloidosis. Combinations of anti-light-chain synthesis and therapies to prevent misfolding are likely the next generation of therapies. The future focus for patients with light-chain amyloidosis is to direct therapy not at the plasma cell clone but fully formed amyloid fibrils. Even with effective therapy persistent amyloid fibrils deposited prior to the diagnosis lead to significant morbidity and impair quality of life. Explorations are underway to look at antibodies that bind to amyloid fibrils and activate phagocytosis. The ability to use both anti-plasma cell-directed chemotherapy and anti-fibril antibodies will open a new dimension into the therapy of amyloidosis.

PART VIII COMPREHENSIVE CARE OF PATIENTS WITH HEMATOLOGIC MALIGNANCIES

CHAPTER 94

KEY CONSIDERATIONS FOR MANAGING INFECTIONS IN THE COMPROMISED HOST

Samuel A. Shelburne, Russell E. Lewis, and Dimitrios P. Kontoyiannis

Advances in the supportive care during the treatment of hematologic malignancies have improved the life expectancy of afflicted patients. However, this progress is increasingly at the expense of developing a wider range of infectious complications caused by drug-resistant organisms. The clinical approach to infections occurring among hematology patients involves consideration of host immune system defects, and skin or mucosal barrier disruptions that predispose patients to infection (Fig. 94.1). This chapter reviews host defense defects specific to hematologic diseases, their associated infections (Table 94.1), and the differential diagnoses of these syndromes (Table 94.2). We also demonstrate how predictable timelines of immunosuppression associated with a hematopoietic stem cell transplant (HSCT) can be anticipated to devise effective prevention, diagnosis, and management strategies of infectious complications.

HEMATOLOGIC CONDITIONS PREDISPOSING TO INFECTION

Malignant Hematologic Disorders

Antineoplastic Therapy

During antineoplastic treatment, cytotoxic agents frequently are administered in combination with other immunosuppressive therapies, such as corticosteroids or radiation therapy. A diverse array of cytotoxic agents, such as methotrexate, cyclophosphamide, 6-mercaptopurine, and azathioprine, impair cell-mediated immunity. Many of the drugs themselves (e.g., cyclophosphamide) also impair humoral responses and profoundly suppress lymphocyte counts particularly when administered at high doses in multiple cycles.[1] Fludarabine, a purine analogue used for chronic lymphocytic leukemia (CLL), myeloid leukemias, lymphoma, and conditioning chemotherapy for HSCT produces prolonged and profound defects in cell-mediated immunity, thereby increasing susceptibility to *Pneumocystis, Mycobacterium*, cryptococcus, *Listeria monocytogenes* and herpes group viruses (herpes simplex virus [HSV], varicella-zoster virus [VZV], and cytomegalovirus [CMV]).[2]

The use of monoclonal antibody therapy for hematologic disorders results in dysfunction of particular aspects of the immune system.[3,4] Rituximab results in a sustained depletion of B lymphocytes for 6 to 9 months and has been specifically associated with reactivation of hepatitis B virus infection.[3] Blinatumomab is a bi-specific T cell engaging (BiTE) anti-CD19 antibody used for the treatment of Philadelphia-chromosome negative relapsed or refractory B-cell precursor acute lymphoblastic leukemia. Following infusion, blinatumomab causes B-cell aplasia, prolonged hypogammaglobulinemia, neutropenia, and may be associated with a cytokine release syndrome (CRS) similar to other T-cell activating therapies. Consideration for immunoglobulin substitution should be considered in patients with severe infections.[5] Alemtuzumab administration causes profound lymphopenia and an increased risk for a variety of viral and fungal infections.

Exogenous administration of glucocorticoids leads to increased susceptibility to infection. The degree of immunosuppression and the relative risk for infection depend on the dose and duration of use. The major effect of steroids on granulocyte function is a decrease in chemotactic activity. This explains, in part, the clinical observation that the signs and symptoms of severe infections may be masked or greatly reduced in patients receiving steroids. Steroids may enhance susceptibility to infection by means of negative effects on glucose homeostasis, wound healing, skin fragility, monocyte and lymphocyte function, production of cytokines, and humoral immune responses.[5]

Radiation therapy has been associated with granulocyte dysfunction and delayed wound healing. Defects in cell-mediated immunity may persist for more than 1 year after intensive radiation therapy or after HSCT.

Acute Leukemias

In patients with acute leukemias, a major cause of morbidity is infection due to drug-associated mucositis and therapy-induced neutropenia. Most infections occurring during neutropenia are bacterial, but patients with prolonged neutropenia are at additional risk for development of yeast and mold infections. Patients with acute leukemia who progress to hematopoietic cell transplant have added risk for infections associated with acquired deficiencies in cell-mediated and humoral immunity, such as *Pneumocystis jirovecii* and CMV infections.[6]

Chronic Leukemias

Infections in patients with chronic myeloid leukemia are most commonly associated with aggressive chemotherapy or HSCT. Host defense defects with tyrosine kinase inhibitors, such as imatinib or dasatinib, have not been well defined.[7] Chemotherapy for blast crisis resembles therapy for acute leukemia. Patients with CLL are predisposed to infection because of immunodeficiency related to the leukemia itself (humoral and cellular immune dysfunction) and to therapy-related immunosuppression.[4] In early B-cell CLL, the infectious risk is mainly related to unbalanced immunoglobulin chain synthesis and resultant hypogammaglobulinemia. In patients with advanced CLL, particularly after the introduction of therapy with purine analogues and monoclonal agents (e.g., rituximab, alemtuzumab), neutropenia

TABLE 94.1 **Malignant and Select Nonmalignant Hematologic Diseases and Their Associated Infection-Predisposing Host Defects**

Hematologic Condition	Infection-Predisposing Host Defects
Acute myeloid leukemia	Neutropenia; therapies such as dose-intensive chemotherapy and hematopoietic stem cell transplant may result in additional anatomic disruptions, cell-mediated defects, and humoral defects
Acute lymphocytic leukemia	Neutropenia; therapy effects similar to acute myeloid leukemia
Hairy cell leukemia	Neutropenia (also monocytopenia); abnormal humoral immunity; T-cell suppressing therapy
Chronic lymphocytic leukemia	Hypogammaglobulinemia; abnormal cell-mediated immunity
Chronic myeloid leukemia	No prominent host defects unless aggressive therapy, advanced stage, or postsplenectomy
Multiple myeloma	Hypogammaglobulinemia; other host defects may occur with aggressive therapy or advanced stage
Hodgkin/non-Hodgkin lymphomas	Abnormal cell-mediated immunity, therapy-related neutropenia, splenic dysfunction (if splenectomy or radiation)
Myelodysplastic syndromes	Functional or absolute neutropenia
Aplastic anemia	Neutropenia; abnormal cell-mediated immunity from immunosuppressive therapies (e.g., steroids, antithymocyte globulin, cyclosporine, hematopoietic stem cell transplantation)
Paroxysmal nocturnal hemoglobinuria	Deficient Fc receptor may contribute to abnormal cell-mediated immunity
Hemolytic states (thalassemia)	Gallstones may serve as a nidus for infection; splenic dysfunction or splenectomy
Sickle cell disease	Can be neutropenic with aplastic crisis; bone infarcts may serve as a nidus for infection; splenic dysfunction with poor complement activation and opsonization from autosplenectomy

and defects in cell-mediated immunity are other factors predisposing to infection. The risk for infectious complications increases with the duration of CLL, reflecting the cumulative immunosuppression related to its treatment. The incidence of infection correlates with the serum levels of immunoglobulins (particularly IgG), which may be further impaired by use of anti-CD20 therapies.

Ibrutinib, the first Bruton tyrosine kinase inhibitor approved for the treatment of CLL, is associated with hypogammaglobulinemia and inhibits B-cell signaling. In clinical trials one-third of patients developed respiratory tract infections, of which 15% were categorized as severe pneumonia requiring hospitalization and intravenous antibiotics.[8] Other opportunistic infections including *P. jirovecii* pneumonia, cryptococcosis, histoplasmosis, and fusariosis, have been reported. *Aspergillus* infections with high rates of central nervous system involvement have been observed in patients receiving ibrutinib for CLL or for primary central nervous system lymphoma.[9–11] At

TABLE 94.2 **Host Defense Impairments and Their Associated Infectious Pathogens**

Host Defense Defect	Pathogen Categories
Neutropenia	Enteric gram-negative organisms
	Gram-positive staphylococci and streptococci
	Anaerobes
	Yeast, particularly *Candida* species
	Molds, particularly *Aspergillus* species
Abnormal cell-mediated immunity	Atypical bacteria: *Legionella, Nocardia*
	Salmonella species
	Mycobacteria (*M. tuberculosis* and atypical mycobacteria)
	Disseminated infection from live bacillus Calmette-Guérin (BCG) vaccine
	Environmental fungi, including *Cryptococcus neoformans, Histoplasma capsulatum, Coccidioides immitis*
	Endogenous yeast, particularly *Candida* species
	Herpesviruses
	Infections from live-virus vaccines
	Pneumocystis jirovecii
	Toxoplasma gondii
	Cryptosporidium
	Strongyloides stercoralis
Immunoglobulin abnormalities	Gram-positive *Streptococcus pneumoniae, Staphylococcus aureus*
	Gram-negative *Haemophilus influenzae*, *Neisseria* species, enteric organisms
	Enteroviruses
	Disseminated infections from live-virus vaccines
	Giardia lamblia
Complement abnormalities C3, C5	Gram-positive *S. pneumoniae*, staphylococci
	Gram-negative *H. influenzae, Neisseria* species, enteric organisms
Complement abnormalities C5–C9	*Neisseria* species
Anatomic disruption	Pathogen categories
Oral cavity	α-Hemolytic streptococci, oral anaerobes
	Candida species
	Herpes simplex virus
Esophagus	*Candida* species,
	Herpes simplex virus, cytomegalovirus
Lower gastrointestinal tract	Enterococcus, gram-negative enteric organisms,
	Anaerobes *(Bacteroides fragilis, Clostridium perfringens)*,
	Candida species, *Strongyloides stercoralis*
Skin (IV catheter)	Gram-positive staphylococci and streptococci, *Corynebacterium, Bacillus*
	Atypical mycobacteria
Urinary tract	Enterococcus
	Gram-negative enteric organisms
	Candida species
Splenectomy	Encapsulated organisms: *S. pneumoniae, H. influenzae, Neisseria, Capnocytophaga canimorsus*
	Salmonella (especially sickle cell disease),
	Babesia

present there are no standard recommendations for antimicrobial or antifungal prophylaxis with ibrutinib therapy.

Idelalisib and duvelisib inhibit B-cell receptor signaling by targeting the delta isoform of phosphoinositide 3-kinase (PI3K). Serious infections have been reported in 20% to 30% of patients with CLL receiving these agents alone or in combination with rituximab, including pneumocystis pneumonia and CMV reactivation. Therefore, a high index of suspicion is important for these infections in patients receiving these agents.

Lymphomas

Hodgkin and non-Hodgkin lymphoma are commonly associated with impaired cell-mediated immunity. The degree of immune impairment may correlate with the extent of disease and often is compounded by administration of immunosuppressive therapy. The intrinsic impairment of cell-mediated immunity in Hodgkin lymphoma can persist even after an apparent cure. Splenectomy-related infections occur with sepsis caused by encapsulated bacterial organisms at a median of 22 months, but sometimes many years after surgery. The risk of viral and fungal infection is elevated in patients who have undergone extensive treatment and are undergoing salvage chemoimmunotherapy after relapsing (typically rituximab-based regimens) followed by autologous HCT or allogeneic HSCT following the relapse.

Myelodysplastic Syndrome

Neutrophils and band forms from patients with myelodysplastic syndrome are functionally defective and probably are derived from a malignant clone of myeloid precursor cells. Neutrophils from patients with myelodysplastic syndrome have deficiencies in myeloperoxidase, elastase, and integrins. A significant portion of myelodysplastic syndrome patients die within 3 years of diagnosis from infections, bleeding complications, or progression to acute leukemia.

Multiple Myeloma

Malignant plasma cells produce a variety of immunomodulatory molecules such as transforming growth factor beta (TGF-β) that suppress B-cell function, which contribute to defects in humoral immunity.[11] Patients having myeloma with IgG paraprotein have an increased rate of catabolism of normal and clonal IgG. They also may have defects in complement and granulocyte function. Cell-mediated immunity is not impaired by the disease but is compromised by corticosteroids or cytotoxic therapy. Prolonged and intense multiple myeloma therapy, including autologous stem cell transplant, can eventually result in a profoundly immunocompromised state resembling that seen in acute leukemia or allogenic stem cell transplant recipients.

Uncommon Malignancies

Patients with hairy cell leukemia frequently develop infections with atypical mycobacteria. Effective treatment of hairy cell leukemia can reverse host cellular immune defects with eradication of mycobacterial infection.

Defects in cell-mediated immunity have been postulated to explain the incidence of infection caused by intracellular pathogens in patients with the relatively rare T-cell malignancies mycosis fungoides and T-cell CLL.

Nonmalignant Hematologic Disorders

Aplastic Anemia

Chronic neutropenia is the main cause of recurrent bacterial and fungal infections among patients. Periodontal infections are particularly common. Treatment of the underlying hematologic disease is required to stop recurrent infections and cure some chronic infections.

Paroxysmal Nocturnal Hemoglobinuria

Patients with paroxysmal nocturnal hemoglobinuria are at some increased risk for bacterial infection due to a deficiency of decay-accelerating factor on the membrane of neutrophils. Modest and progressive granulocytopenia, progression to aplasia or leukemia may compound these risks. Vaccination against meningococcus is required before treatment with the terminal complement inhibitor eculizumab.

Granulocytic Phagocyte Disorders

The clinical approach to infections in patients with granulocytic phagocyte disorders is specific to each of these disorders and is beyond the scope of this chapter. However, chronic granulomatous disease is discussed because patients with this congenital immunodeficiency who survive into adulthood are at risk for severe infections. Chronic granulomatous disease is a heterogeneous group of disorders resulting from defective or malfunctioning oxidative metabolism capacity of phagocytes. Recurrent infections with bacteria and fungi are common and occasionally life threatening, despite optimal antimicrobial therapy. Infections with *Staphylococcus* species and *Aspergillus* species can be particularly aggressive.[12] Granulomata may form in response to infection, especially in the gastrointestinal (GI) and genitourinary tracts.

Erythrocyte Disorders

Glucose-6-phosphate dehydrogenase deficiency is a sex-linked disorder. Deficiency of this enzyme limits glucose metabolism through the hexose monophosphate shunt, resulting in an abnormal respiratory burst in neutrophils. Bacterial infections can occur if the deficiency is severe.

Hemoglobin Gene Variants

Patients with chronic hemolytic states may develop bilirubin gallstones, which can serve as a nidus for infection. Defects in cell-mediated immunity have been described in patients with thalassemia. Patients with sickle cell disease have an increased susceptibility to bacterial infections.[13] Defective alternative complement pathway function, especially in conjunction with asplenia, contributes to the propensity to bacterial infection. Splenic involution results in depressed synthesis of the alternate pathway factor(s) of complement and decreased phagocytic clearance of bacteria. Phagocytosis of *Streptococcus pneumoniae* is abnormal, in part because of an inability to use the alternate pathway for C3 fixation as a means of opsonization. An increased risk for *Salmonella* infection appears to be unique to the sickle cell population. Suppurative arthritis can occur after repeated episodes of hemarthrosis among patients with sickle cell disease.

Coagulation Disorders

Hemophilias are sex-linked deficiencies of clotting factor VIII or IX. Septic arthritis should be considered in the differential diagnosis of any hemophiliac with repeated episodes of hemarthrosis whose articular signs and symptoms fail to improve quickly after administration of appropriate coagulation factor replacement.

Blood Groups

The Duffy blood group antigen serves as a receptor for *Plasmodium vivax* to invade erythrocytes. Blood group O is associated with *Helicobacter pylori* infection and an associated increase in peptic ulceration because the Lewis (b) blood group antigen mediates *H. pylori* attachment to human gastric mucosa.

Host Defense Impairment and Associated Infection Issues

Neutropenia

Infection rates increase when neutrophil counts fall below 1000/mm^3, but the patient is most at risk for spontaneous infection when the count is below 100/mm^3 (Fig. 94.2). The patient who is neutropenic from cytotoxic therapy can serve as a basic model for predicting infections that could occur in other patients with qualitative or quantitative granulocyte defects.

Neutropenia predisposes to the development of bacterial and fungal infections but does not appear to increase the incidence or severity

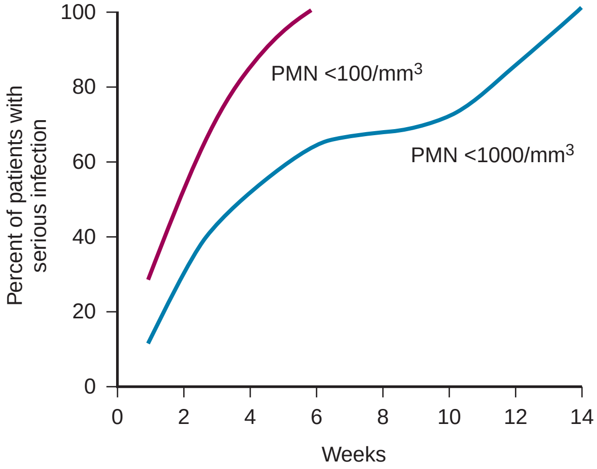

Figure 94.2 RELATIONSHIP OF SEVERITY AND DURATION OF NEUTROPENIA TO THE RISK FOR DEVELOPING A SERIOUS INFECTION. *PMN*, Polymorphonuclear neutrophil. *(Courtesy GE Body.)*

of viral and parasitic infections. Patients with profound and prolonged neutropenia who are at particular high risk for infection (e.g., cytopenic patients with acute myelogenous leukemia and severe mucositis following induction therapy) are likely to benefit from receiving prophylactic antimicrobials.[14,15] However, patients with moderate granulocytopenia (i.e., absolute granulocyte counts in the range from 500 to 2000/mm^3 that are not falling precipitously) should not receive prophylactic antimicrobial agents. Colony-stimulating factors (granulocyte colony-stimulating factor [G-CSF; pegylated filgrastim], granulocyte-macrophage colony-stimulating factor [GM-CSF, sargramostim]) are routinely used in the management of hematologic disorders. A number of functional granulocyte parameters may be enhanced by G-CSF or GM-CSF, including enhanced per-cell phagocytosis, oxidative metabolism, microbicidal activity, and antibody-dependent cytotoxicity.[16] However, G-CSF or GM-CSF administration may decrease the motility of granulocytes, impair in vivo migration, and decrease bacteria-induced chemotaxis. The clinical significance of any of these effects remains to be established but is generally believed to be insignificant in light of the potency of these agents in shortening the depth and duration of therapy-induced neutropenia.

Defects in Cell-Mediated Immunity

Cellular immune dysfunction occurs in patients with lymphoid malignancies, in those with hematologic malignancies undergoing HSCT, and in patients with AIDS. The most frequently encountered pathogens are intracellular organisms because they can survive and even replicate inside macrophages in a non-immune individual or in the absence of T-cell immunity. Specific pathogens associated with infection in patients with cell-mediated immunity include bacteria (including *Mycobacterium tuberculosis*, atypical mycobacteria, *Salmonella*, streptococci, *Legionella, Nocardia*, and *Listeria*); fungi (including the yeasts *Candida* and *Cryptococcus;* molds such as *Aspergillus;* endemic dimorphic fungi such as *Histoplasma* and *Coccidioides;* and *Pneumocystis*); viruses (including herpes group viruses [HSV, VZV, CMV] and respiratory viruses); and protozoa (*Toxoplasma gondii, Cryptosporidium*, and *Strongyloides stercoralis*).

Patients with defects in cell-mediated immunity or who are about to receive HSCT should undergo risk factor assessment for reactivation of tuberculosis. Patients with a known history of an untreated but positive Mantoux test or interferon-gamma release assay should receive prophylactic isoniazid to prevent reactivation and potential dissemination of tuberculosis. Patients without a prior Mantoux test but with risk factors for tuberculosis should undergo a screening test for latent tuberculosis before starting the conditioning regimen for HSCT.

Patients with defects in cell-mediated immunity are at risk for the development of disseminated infection due to live vaccines, even when the vaccine contains attenuated organisms. Accordingly, these patients should not receive vaccines containing bacillus Calmette-Guérin (BCG), live varicella, measles, mumps, rubella, yellow fever, or oral polio. HSCT recipients are eligible for revaccination with some of the live virus vaccines 2 years after transplantation, provided the patient does not have graft-versus-host disease (GVHD), or is not receiving ongoing pharmacologic immunosuppression (see Chapter 110, Table 110.4).

Defects in the Humoral Immune System

Patients with primary or secondary defects, or deficiencies in humoral immunity, such as deficiencies in immunoglobulin or complement, are susceptible to recurrent pyogenic infections from polysaccharide-encapsulated bacteria, such as *S. pneumoniae, Haemophilus influenzae*, and *Neisseria* species. HSCT recipients who continue to receive immunosuppressive therapy more than 100 days after transplantation should be given antimicrobial prophylaxis with coverage for encapsulated bacteria until immunosuppression is discontinued. Patients are also at risk for infections from enteroviruses and *Giardia lamblia*. Patients with low levels of circulating IgG may benefit from intravenous Ig (IVIg) infusions, although the benefit of using of IVIg infusions for routine prophylaxis must be weighed against the expense of this approach.

Abnormalities in Splenic Function

A number of hematologic disorders are complicated by either intrinsic splenic impairment or splenectomy. The spleen removes organisms from the blood that have been ineffectively opsonized by complement, serving an adjunctive role in fighting infection. Alternate complement pathway defects may be particularly important in patients with splenic dysfunction associated with sickle cell disease.

Asplenic or splenectomized patients are at increased risk for serious, frequently fulminant, bacterial infections, primarily caused by *S. pneumoniae, H. influenzae, Neisseria, Babesia*, and *Capnocytophaga canimorsus*. The initial presentation of even overwhelming infection can be subtle, with fever often the only sign. Accordingly, all asplenic patients with underlying hematologic disease who present with fever should be managed initially as potentially septic. Overwhelming infection after splenectomy occurs in approximately 7% of postsplenectomy patients, with 50% of infection-related deaths occurring in the first 3 months.[17] Prophylaxis against pneumococcal infection is used for asplenic patients who are small children or for those with increased immune impairment from malignant disease.

Pneumococcal, *H. influenzae* type b, and meningococcal vaccines should be administered to asplenic patients. Patients with an intact spleen may respond better to pneumococcal polysaccharide vaccine than do splenectomized patients, so immunization is recommended as early as possible before elective surgery. Additionally, immunization before splenectomy can result in protective pneumococcal antibody titers immediately after the operation. For patients with Hodgkin lymphoma, the antibody response to pneumococcal vaccine may not be affected by the timing of immunization relative to splenectomy. Immunizations reduce, but do not eliminate, the risk for serious infection with encapsulated bacteria.

Infections Associated With Immunotherapy

The use of immunotherapeutic agents for hematological malignancies, such as checkpoint inhibitors and chimeric antigen receptor T cell (CAR-T) cells, have shown considerable promise in the treatment of a wide spectrum of malignancies. A comprehensive workup of autoimmune/organ-specific disease, endocrinopathy, or infectious diseases is important before immunotherapy is initiated, as inflammatory responses are strongly induced against these conditions during checkpoint therapy. Although any organ system can be affected, immune-related adverse events associated with checkpoint inhibitors most commonly involve the GI tract, endocrine glands, skin, and liver.[18] Less frequently, the central nervous system and cardiovascular, pulmonary, musculoskeletal, and hematologic systems are involved. Whenever symptoms of immune-related adverse events are present, infections involving these organ systems must be ruled out, as infections can mimic or co-exist alongside immune-driven processes. In more severe cases, glucocorticoids or an anti-TNF-α antibody, infliximab are used, which can increase the patient's risk for developing opportunistic infections including invasive pulmonary aspergillosis, CMV, hepatitis, and pneumocystis pneumonia.

The most commonly observed toxicity with CAR-T therapy is CRS, which ranges in severity from low-grade constitutional symptoms to life-threatening multiorgan dysfunction.[19] Less frequently, severe CRS can evolve into fulminant hemophagocytic lymphohistiocytosis/macrophage activation syndrome (HLH/MAS). CAR-T-cell–related encephalopathy syndrome (CRES) can also develop concurrently or after CRS.[19] CRS is typically treated initially with the anti-IL6 agent tocilizumab, but in more severe cases (Grade III/IV) requires treatment with corticosteroids.

Patients receiving therapy with CAR-T cells are considered to be at high risk for infection due to cumulative immunosuppression associated with the underlying malignant disease and its treatment, as well as the cytotoxic and lymphodepleting chemotherapy administered prior to the cell infusion.[20] In addition, the infusion of CAR-T cells depletes normal CD19$^+$ B cells, which results in prolonged hypogammaglobulinemia that can persist over time.[21] Patients are at high risk for recurrent and severe bacterial and viral respiratory infections. Invasive fungal disease, including invasive candidiasis and invasive aspergillosis have been reported in patients requiring steroid treatment for CRS.[22]

Anatomic Alterations in Host Defense

Immunocompromised patients frequently have disruptions in the skin and mucosa, which are important primary physical barriers against endogenous and exogenous sources of infections (see Fig. 94.1). Disruption of skin and mucosa may result from invasion by malignant cells, the effects of chemotherapy or radiation therapy, the use of invasive diagnostic or therapeutic procedures (e.g., intravenous catheters), and from the effects of local infections, such as oral HSV. Such alterations may provide a nidus for microbial colonization, a focus for localized infection, and a portal of entry for systemic invasion. Organisms associated with defects in skin or mucosal surfaces depend on the site of the breakdown, local colonizing flora, and other factors. Gram-positive organisms are associated with isolated disruption of the skin from an indwelling intravenous catheter, usually with coagulase-negative staphylococci, but also with *Corynebacterium jeikeium, Bacillus* species, and occasionally atypical mycobacteria.

GI mucosal integrity is frequently disrupted by chemotherapeutic agents. Because the GI tract normally is colonized by a multitude of organisms, this state can lead to infection by streptococci, aerobic gram-negative enteric and anaerobic bacteria, and yeast. Mucosal damage can allow normal flora to invade and become pathogens. Lower GI ulcerations permit infections by *Bacteroides fragilis* or *Streptococcus bovis*. Oral lesions are associated with HSV reactivation, ulceration, and possible bloodstream infection with other common oral flora such as α-hemolytic streptococci. Mucosal integrity also depends on resident gut bacteria production of a number of metabolites and bioproducts necessary to maintain homeostasis in the host. When chemotherapy and/or antibiotic therapy are administered, the associated dysbiosis of the gut microbiome may trigger local inflammation, or alternation of the host immune response against malignant cells and pathogens.[23] Strategies aimed at modulation of host-microbiome interactions to improve cancer treatment, or to reduce infection risk have become a major research focus.

The genitourinary tract mucosa may be disrupted by tumors, invasive procedures, or cytotoxic therapy, with subsequent colonization and the potential for local or invasive infection. The most common urinary tract pathogens are enteric gram-negative bacilli, enterococci, and *Candida albicans*. Viral reactivation is common, predominantly from adenovirus and polyomavirus (BK virus), but also from the herpesviruses (HSV and CMV).

The lung, genitourinary tract, biliary tract, and auditory canal are potential sites of mechanical obstruction, increasing the risk for localized infection. Obstruction may lead to stasis of local body fluids, with resultant overgrowth of potentially pathogenic colonizing organisms. Patients with chronic hemolytic states are prone to gallstones that can become a nidus for infection.

Infection in Patients With Acute Neutropenia or Lymphopenia Following Chemotherapy or Transplantation

This section outlines predictable infections that can present during acute profound neutropenia/lymphopenia.

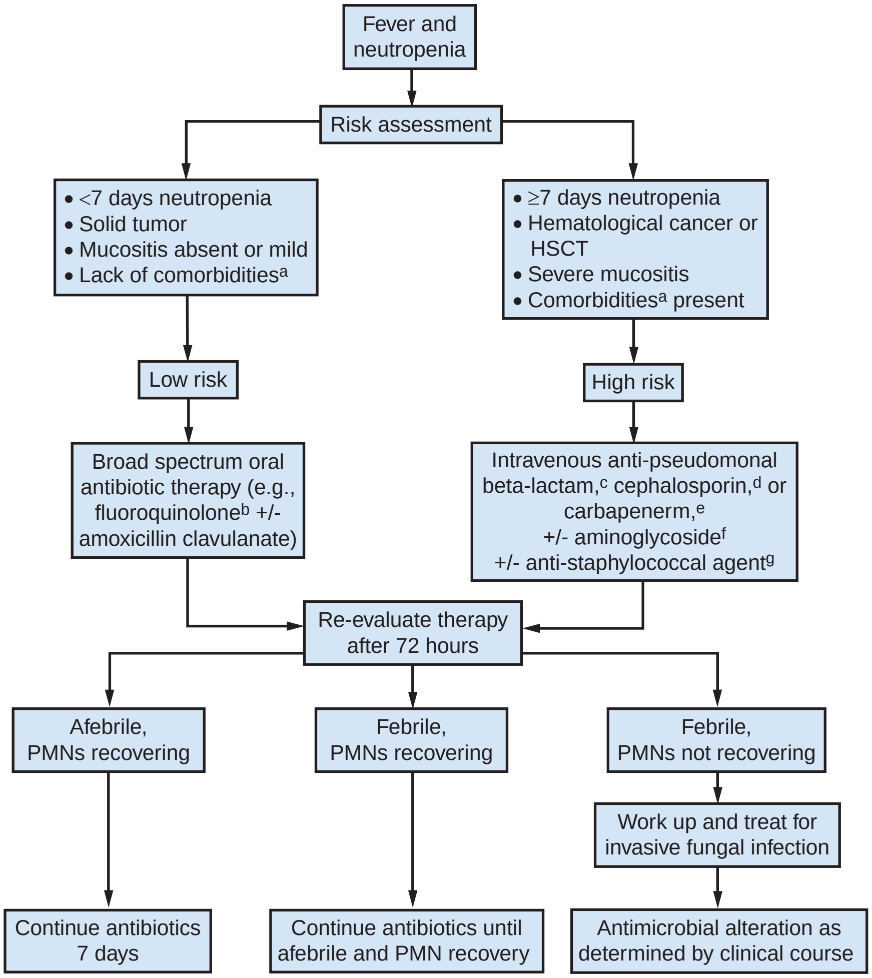
Fever

Despite the specific prophylactic measures directed against common pathogens, many fevers occur in neutropenic patients after transplantation or chemotherapy. Fevers can be divided into three categories: infectious fever with an obvious source, infectious fever without an obvious source, and noninfectious fever. Risk factor assessment should include knowledge of the temporal relationship to blood product infusions; recent exposure to contagious infection; temperature of the fever and whether the fever is accompanied by chills, rigors, or diaphoresis; and response to antipyretics. Symptom assessment should include evaluation to assess sinus drainage, sore throat, ear pain, cough, sputum production, shortness of breath, abdominal pain, diarrhea, rash, and dysuria.

The initial workup of a fever in a patient with neutropenia, regardless of whether or not an infectious or non-infectious source is suspected, is identical and includes blood culture, culture of symptom-related sites (e.g., sputum, urine, with/without stool, with/without cerebrospinal fluid), review of the medication list for potential contributors to drug fever, review of recent transfusions, chest radiograph, and computed tomography (CT) scan of any symptom-related body systems. When feasible, blood cultures should be drawn through an existing indwelling catheter as well as peripherally because this can facilitate the diagnosis of a catheter-related bloodstream infection compared to a bloodstream infection arising from a different source (e.g., the GI tract).[24]

Consensus guidelines on the management of patients with febrile neutropenia have been published.[24,25] Empiric antibiotics are recommended for all febrile patients with neutropenia, but the type of antibiotics and the site of administration (i.e., hospital vs. outpatient) depends on the severity of immunosuppression, expected duration of neutropenia, and factors related to the local epidemiology and resistance patterns (Fig. 94.3). Patients defined as low-risk using the Multinational Association for Supportive Care in Cancer (MASCC) index can be treated as outpatients, whereas other patients are generally admitted for intravenous therapy.[26,27] Typical pathogens causing infection in this situation include Enterobacteriaceae*, Pseudomonas, Streptococcus*, and *Staphylococcus* spp. Thus, antipseudomonal β-lactam antibiotics such as ceftazidime or cefepime, piperacillin-tazobactam, and carbapenems are commonly employed as empiric therapy. The selection of antibiotic therapy depends on local susceptibility patterns and whether the fever developed after previous antibiotic treatment. Vancomycin is administered if staphylococcal disease is suspected, or if the patient is clinically unstable while cultures are pending. Severely ill patients are often also treated with an aminoglycoside for the first 48 to 72 hours of illness, although there is limited evidence supporting this approach.[27]

Therapeutic changes to the antimicrobial regimens are made in response to culture results, but cultures are negative about 50% of the time (see Fig. 94.3). If the patient becomes afebrile, therapy is



Fever and neutropenia
Risk assessment
• <7 days neutropenia
• Solid tumor
• Mucositis absent or mild
• Lack of comorbidities[a]
• ≥7 days neutropenia
• Hematological cancer or HSCT
• Severe mucositis
• Comorbidities[a] present
Low risk
High risk
Broad spectrum oral antibiotic therapy (e.g., fluoroquinolone[b] +/- amoxicillin clavulanate)
Intravenous anti-pseudomonal beta-lactam,[c] cephalosporin,[d] or carbapenerm,[e] +/- aminoglycoside[f] +/- anti-staphylococcal agent[g]
Re-evaluate therapy after 72 hours
Afebrile, PMNs recovering
Febrile, PMNs recovering
Febrile, PMNs not recovering
Work up and treat for invasive fungal infection
Continue antibiotics 7 days
Continue antibiotics until afebrile and PMN recovery
Antimicrobial alteration as determined by clinical course

a Hypotension, altered mental status, neurologic changes, respiratory failure, abdominal pain, hemorrhage, cardiac compromise or new arrythmia, catheter tunnel infection, extensive cellulitis, acute renal or liver failure
b Institution sensitivity–dependent, ciprofloxacin, levofloxacin, moxifloxacin
c Drug selection and dosing institution-specific: piperacillin tazobactam, ticarcillin/clavulanate
d Drug selection and dosing institution-specific: ceftazidime
e imipenem, cefepime/cilastatin, meropenem, doripenem
f Gentamin, tobramycin, or amikacin
g Drug selection and dosing institution-specific: vancomycin, linezolid, daptomycin, ceftaroline

Figure 94.3 APPROACH TO PATIENT WITH FEVER AND NEUTROPENIA. *HSCT*, Hematopoietic stem cell transplant; *PMN*, polymorphonuclear neutrophil.

usually continued for 7 days. Persistent fever after more than 72 hours of empiric therapy suggests an untreated infection. If the patient is recovering his or her neutrophil count, no additional changes in antibiotics are typically needed. However, the persistently neutropenic and febrile patient may have an occult fungal infection such as candidiasis or aspergillosis. Thus, empiric antifungal therapy with anti-mold activity (e.g., liposomal amphotericin B or voriconazole or isavuconazole) is recommended.

Two common anaerobic infections occur during neutropenia at sites where biopsy is difficult or contraindicated. Neutropenic enterocolitis, also known as typhlitis, manifests as fever, abdominal pain, and tenderness. A CT scan of the abdomen shows signs of right-sided colonic and ileal inflammation.[16] Excessive soft tissue swelling of the neck during mucositis can be present as a Ludwig angina variant. Broadly active anti-anaerobic, aerobic, and possibly antifungal antimicrobial agents should be added for either of these clinical findings.

Pulmonary Infiltrates

Pulmonary infections are common in the immunocompromised host (see box on Approach to Pulmonary Infiltrates). Plain chest radiography is a good initial screening test but lacks the sensitivity of CT, which generally provides more useful information in terms of characterizing the nature of an infiltrate, and assists the pulmonologist in determining where to direct the bronchoscope for highest yield. A specific infectious and noninfectious differential diagnosis exists for certain radiologic signs (Table 94.3). For example, consolidative focal airspace disease is associated most typically with a bacterial pneumonia. A halo of interstitial changes around a pulmonary nodule or an air crescent above a pulmonary nodule is suggestive of invasive aspergillosis (Fig. 94.4).[28] Although 90% of pulmonary nodules are due to fungal pneumonia (mainly aspergillosis), 10% have various etiologies, including septic bacterial emboli, *Nocardia, Legionella*, mycobacterial infection (with cavitation), Epstein-Barr virus (EBV)–related

APPROACH TO PULMONARY INFILTRATES

Pulmonary infiltrates can be divided into three general categories: consolidative, interstitial, and nodular. A consolidative infiltrate may be bacterial, even polymicrobic, so sampling of the infiltrate through sputum or endotracheal tube suctioning for bacterial and fungal cultures is required. If either of these methods does not provide an adequate sample, “early” (within 72 h) bronchoscopy is indicated. If interstitial or nodular infiltrates are not peripheral (i.e., within the range of the bronchoscope), they should also be evaluated with timely bronchoscopy. An advantage of bronchoscopy, in addition to the ability to obtain a deep specimen, is that the samples usually are sent for a broad range of diagnostic tests. These tests usually are ordered from preprinted order sheets, which reduce errors. Most preprinted order sheets for bronchoalveolar lavage fluid will test for the following:

- Cytology, with the attendant Fite and Gomori methenamine silver stains
- Bacterial (Gram) stain and aerobic culture
- Mycobacterial (acid-fast bacillus) stain and culture
- Fungal (potassium hydroxide or calcofluor) stain and culture
- *Aspergillus* galactomannan antigen
- *Nocardia* culture
- *Legionella* culture
- Viral cultures for herpes viruses and respiratory viruses
- Rapid test for cytomegalovirus (polymerase chain reaction [PCR])
- Rapid test for respiratory viruses during respiratory virus season (pooled respiratory virus shell vial, respiratory syncytial virus antigen, influenza A/B antigen, severe acute respiratory syndrome coronavirus 2)

Optional tests that can be requested from bronchoalveolar lavage fluid, some at significant extra expense, include the following:

- Mycobacterial stain (requires separate 5 mL volume that cannot be used later for culture)
- *Mycoplasma pneumoniae* PCR
- *Chlamydia pneumoniae* PCR
- Human herpesvirus type 6 PCR
- Human metapneumovirus PCR
- Any of the above first-tier tests that your institution does not send on a routine basis (e.g., *Nocardia* or *Legionella*)

Invasive sampling may be the only definitive means for making a diagnosis of peripheral nodules. The two main options are percutaneous fine-needle aspiration and open lung biopsy (usually obtained through video-assisted thoracoscopic surgical procedure). In toto sampling of a lung nodule permits enough material for the whole range of the above diagnostic tests as well as histopathology. Of note, fewer lobectomies of unilateral pulmonary nodular infiltrates have been reported in recent years, probably a result of the frequent use of a broad range of less toxic antifungal therapies.

TABLE 94.3 Pulmonary Infiltrates and Their Association With Specific Infectious and Noninfectious Etiologies

Radiologic Sign	Differential Diagnosis
Interstitial infiltrates	Pulmonary edema
	Diffuse alveolar damage
	Idiopathic pneumonia syndrome
	Respiratory viruses: respiratory syncytial virus, parainfluenza, influenza, adenovirus, enterovirus
	Herpes viruses: cytomegalovirus, herpes simplex virus, varicella zoster virus, human herpes virus type 6
	Pneumocystis pneumonia
Focal airspace disease	Bacterial pneumonia
	Fungal pneumonia
Nodules	Fungal pneumonia (aspergillosis)
	Nocardia
	Legionella
	Septic bacterial emboli
	Mycobacterial infection (with cavitation)
	Epstein-Barr virus lymphoproliferative disorder
	Relapsed malignancy
	Pulmonary embolism (pleural based)

lymphoproliferative disease, relapsed malignancy, and pulmonary embolism (pleural based). Interstitial infiltrates can be caused by either respiratory viruses during the winter season (except for parainfluenza virus, which is nonseasonal), herpes viruses, *P. jirovecii*, edema, or an idiopathic etiology. A complete differential of causes of interstitial pneumonitis (a pulmonary syndrome often associated with HSCT) is given in Chapter 110.

Pulmonary and sinus infections from inhaled molds are more likely to occur as the duration of neutropenia extends beyond 21 days.[29] For this reason, among HSCT recipients without graft failure, invasive tissue mold infections occur at a low rate (less than 3%) before engraftment because of the environmental preventive measures taken for air filtration. However, if endogenous occult aspergillosis infections are present before HSCT, the infection can rapidly escalate when the immune system is profoundly suppressed by the conditioning regimen. This phenomenon manifests as early invasive aspergillosis (before day 40). Therefore, patients with hematologic malignancy at risk for occult mold infections in the lungs, sinuses, and at times, the oral cavity should have CT scans of the lungs and sinuses before the onset of any profoundly immunosuppressive regimens, such as HSCT and select nontransplantation regimens. High-risk patients should be given mold-active antifungal prophylaxis to either prevent or suppress invasive mold infections.

Bacteria
